SUMMARY Alkaline phosphatase (ALP) activities were compared in fibroblasts from three cystic fibrosis patients and two normal controls after culturing the cells in normal growth medium and in medium containing Tamm-Horsfall glycoprotein, isoproterenol, and theophylline. No consistent alterations in ALP activities were noted, either between the same cell lines grown under different conditions, or between normal and cystic fibrosis cell lines. It is concluded that it is not possible to use changes in ALP activity in cultured cells for the prenatal diagnosis of cystic fibrosis.

It has recently been reported that the metabolism of cultured fibroblasts from patients with cystic fibrosis (CF), but not that of heterozygotes or normal controls, can be modified by growing the cells in the presence of a specific urinary glycoprotein, the Tamm-Horsfall glycoprotein (THP). Data have been presented which show that under these conditions there is induction of alkaline phosphatase (ALP, E.C.3.1.3.1) resulting in an up to seven-fold higher specific activity in CF fibroblasts compared to normal control fibroblasts. A possible mechanism for this induction process has been suggested and a hypothesis on the basic biochemical defect in CF advanced. Because of the important implications of this hypothesis for the prenatal diagnosis of this most frequent lethal inherited disease of childhood, we have pursued the observation of induced ALP activity in fibroblast cultures from CF patients, duplicating as closely as possible the culture conditions and microassay techniques described. In repeated experiments, we have not been able to find reproducible differences in ALP activity between fibroblasts from CF patients and normal subjects.

Materials and methods

PREPARATION OF TAMM-HORSFALL GLYCOPEPTIDE
Extraction was from urine according to the original method, except that sodium azide (0.02% final concentration) was included in the collection vessel instead of chloroform as an antibacterial agent. Clean, sterile glassware was used throughout. The final preparation obtained was an almost clear, viscous liquid. Four separate batches were prepared and the concentration of the dissolved glycoprotein measured spectrophotometrically. After removal of a small aliquot for ALP estimation, the remainder of the glycoprotein was stored at 4°C with the addition of kanamycin (100 μg/ml) to prevent decomposition through bacterial growth.

FIBROBLAST CULTURES
Fibroblast cell lines derived from skin biopsies taken from three unrelated female patients with CF (CF1, 8 years; CF2 and CF3, 9 years) and from two healthy adult donors (aged 22 and 24 years) were used in the induction experiments. CF cultures between the 12th and 14th passage and control cultures between the 18th and 20th passage were trypsinised and approximately 150 000 cells seeded into 20 cm² Petriperm (Heraeus) culture dishes. These are disposable petri dishes the bottom of which is formed by a 25 μm-thick transparent membrane which serves as the culture surface. Three dishes were set up for each cell line and after overnight incubation to allow the cells to attach, the medium was removed and replaced as follows for each cell line: medium A: Ham's F10 with 15% fetal calf serum (FCS) and penicillin/streptomycin; medium B: medium A plus 100 μg/ml THP; medium C: medium B plus 1 × 10⁻⁶ mol/l
isoproterenol and $1 \times 10^{-3}$ mol/l theophylline. Culture was continued for 72 hours at 37°C in a fully humidified atmosphere containing 5% CO$_2$ in air, with additional doses of isoproterenol (sterilised by filtration) added to medium C to a final concentration of $1 \times 10^{-6}$ mol/l 24 hours and 48 hours after the beginning of the induction experiment to supplement its rapid oxidation at 37°C. After 72 hours the medium was removed, the cells washed with isotonic saline, and the dishes shock-frozen in liquid nitrogen and freeze dried. After lyophilisation, the dishes were stored in closed boxes containing silica gel in a temperature and humidity controlled room (20°C; <40% relative humidity) until required for ALP assay.

In addition, all three CF cell lines and one control cell line were set up in triplicate in 25 cm$^2$ Falcon flasks and cultured with normal medium A and both induction media B and C under the same growth conditions as the Petriperm cultures. The cells were harvested after 72 hours by trypsinisation and pellets prepared for ALP assay.

**ALKALINE PHOSPHATASE ASSAYS**

ALP activity of freeze dried fibroblasts, cell pellets, and THP preparations was assayed using the artificial substrate 4-methylumbelliferyl-phosphate (Mu)(Koch-Light), final concentration 5-5 mmol/l, in 0.2 mol/l 2-amino-2-methyl propadiol buffer pH 9.3, with 0.05% bovine serum albumin.

The assay of ALP activity in freeze dried fibroblasts was carried out in parafilm microcuvettes (PMC)$^8$ containing 0.3 µl substrate and loaded with 20 freeze dried fibroblasts isolated by free hand dissection of a small piece of the Petriperm membrane carrying the freeze dried cells. After incubation for 2 hours at 37°C, the reaction was ended by washing the contents of each PMC into 500 µl carbonate buffer (0.5 mol/l, pH 10.7) and the liberated fluorescence measured in a Perkin Elmer MPF-2A fluorimeter (excitation 365 nm, fluorescence 448 nm).

The cell pellets obtained from the parallel culture experiment in Falcon flasks were disrupted by sonication in 100 µl distilled water, aliquots were further diluted 1:10 with distilled water, and 1.0 µl aliquots assayed for ALP activity using the same substrate concentration as above in a final volume of 2.0 µl under oil. Protein content of the diluted lysates was estimated by the method of Lowry et al.$^6$ Additional assays using the same cell lysates were performed with 10-0 mmol/l MgCl$_2$ as a component of the substrate solution.

ALP activity was measured in each of the THP preparations using the PMC techniques described above, with 0.3 µl THP and 0.3 µl substrate (final substrate concentration as above, but without MgCl$_2$).

## Results

A specific ALP activity was found in three THP preparations of 15-1, 16-8, and 17.9 mmol Mu/h/mg THP, respectively. The level of ALP activity per ml of an induction medium containing 100 µg/ml of a particular THP preparation is one-tenth of these specific activities. Bacterial contamination in a fourth THP preparation resulted in an approximately 16 times higher level of ALP activity.

Table 1 contains the results of the ALP assays in cell homogenates after induction experiments in the three CF cell lines and one control cell line. Enzyme activity is expressed as mol Mu/h/dry weight of 20 fibroblasts to facilitate comparisons with the ALP assays in freeze dried cells (table 3). The conversion

factor used was 1·0 mg homogenate protein = 3·0 \times 10^6 fibroblasts.\textsuperscript{7} The presence of Mg\textsuperscript{2+} ions in the substrate has an activating effect on ALP activity of freshly prepared fibroblast lysates. In one cell line, CF2, there was a marked increase in ALP activity in cells cultured in medium C containing THP, isoproterenol, and theophylline compared with cells cultured in normal medium A. However, the induction medium B containing 100 \mu g/ml THP had apparently no particular stimulatory effect on ALP activity in any of the cell lines tested. When ALP activity was restested in three lysates of CF2 which had been stored frozen at −20°C, similar relative values were obtained between the three different cultures, both immediately after thawing the sample and at the higher specific activities observed after the thawed sample had been allowed to stand at room temperature for 48 hours (table 2). This time dependent increase in ALP activity of thawed enzyme preparations has been previously reported.\textsuperscript{8}

In contrast to the results obtained with cell homogenates, the presence of Mg\textsuperscript{2+} ions in the substrate was found to have no apparent activating effect on ALP activity of the freeze dried fibroblasts dissected from the Petriperm dishes. The results presented in table 3 have been obtained without MgCl\textsubscript{2} in the substrate. One CF cell line (CF2) had increased ALP activity in those cells cultured under conditions intended to be permissive for the induction of ALP (media B and C), but a similar rise also occurred in the two control cell lines and the extent of the increase in activity varies between individual experiments. ALP activities in CF1 and CF3 also appear to be independent of the culture conditions.

Individual ALP activities are the means of 10 independent assays with 20 freeze dried fibroblasts each, measured without exogenous Mg\textsuperscript{2+} in the substrate. Each cell line was tested twice (CF2 three times), using different THP preparations in the induction medium.

### Discussion

In our series of cultures, no consistent pattern of induction of ALP emerges similar to that described by Hösli et al,\textsuperscript{1} which would allow a distinction to be made between cultured cells from CF patients and controls. A possible reason for this discrepancy may be minor differences in the composition of the THP or in the presence of impurities, both of which could be crucial to the action of the induction medium. The three THP preparations used in this study were ineffective as ALP inducers. There are also conflicting reports on the influence of isoproterenol stimulation of cyclic AMP in CF cell cultures\textsuperscript{9,10}, which has been proposed as the precursor of the increased ALP activity noted by Hösli and Vogt.\textsuperscript{5} In addition, there may be biochemical differences between fibroblast cultures from different CF patients, but since the biochemical defect responsible for CF has not yet been elucidated, it is not at all certain that the metabolic abnormality is expressed in cultured cells.

While our results show only small and inconsistent changes in ALP activity, interpretation of radically altered enzyme levels may also prove difficult. Generalised increases in leucocyte, but not fibroblast, ALP activity occur in Down's syndrome\textsuperscript{11} and other cases of aneuploidy, while there is decreased ALP activity of leucocytes in chronic myeloid leukaemia; these are just some examples of the unspecific response of ALP to a variety of conditions. Also, there are several reports of raised fibroblast ALP activities in vitro under various modified or suboptimal culture conditions;\textsuperscript{12-14} two distinct forms of ALP in fibroblasts have been identified which respond differently to inhibition by L-phenylalanine and activation by Mg\textsuperscript{2+} ions.\textsuperscript{14} In addition, very wide ranges of fibroblast ALP using 4-methylumbelliferyl-phosphate as substrate have been reported. Mulivor et al\textsuperscript{15} found a range of activity equivalent to 1·5 to 136·6 \times 10^{-13} mol Mu/h/20 fibroblasts in a group of seven normal controls, and Vanneuville et al\textsuperscript{16} of 0·5 to 51·4 \times 10^{-13} mol Mu/h/20 fibroblasts in 33 controls. It is likely that similar wide ranges also exist in CF fibroblasts and in amniotic fluid derived cell cultures.

In conclusion we feel that the qualitative and quantitative variations of fibroblast ALP make it an unsatisfactory parameter of induced biochemical abnormalities in CF cell cultures. In particular, there are inherent dangers in the use of a variable marker (ALP activity) for the detection of a particular gene mutation where the marker is not a direct product or characteristic of the defective gene.
DAA thanks the Talbot-Crosbie bequest, University of Glasgow, for financial support and Professor Dr H Galjaard for the facilities to perform these experiments in his laboratory† and for critical reading of the manuscript.
