A pericentric inversion duplication of the subcentromeric region of chromosome 12q

The proband, a 1 year old girl, was referred because of dysmorphic features and developmental delay. There was no family history of congenital abnormalities and the mother had received no drugs during her pregnancy.

The mother was 25 and the father 26 years old at the time of the birth. The pregnancy was normal and the birth uncomplicated. She learnt to sit at 3 months and to crawl at 5 months. She now walks unaided, yet she does not talk or make any sounds. She appears to understand what is said to her. The only abnormalities are a large protruding tongue and epicanthic folds.

Cultured peripheral lymphocytes were used for chromosomal analysis with GTG and R banding. All 15 cells examined showed an elongation of the short arm of one of the chromosomes 12. This was evaluated in the G banded slides as an inverted duplication in the short arm of the immediate subcentromeric region of the long arm: dup(12p)(q11→q12) (figure). The chromosomes of both parents were normal.

Partial trisomy 1q25→qter

A male infant, birth weight 2.78 kg, gestation 38 weeks, with chromosomally normal parents, had a karyotype 46,XY,-17,der(17),t(1;17)(q25;p13) (figure). Clinical findings included moderate enlargement of the cranium with a prominent forehead nevus, long philtrum, thin upper lip, very small palpebral fissures, irregular gums, large asymmetrical ears, undescended testes, hypoplastic scrotum, bifid right thumb, syndactyly of the second and third toes of the left foot, and rockerbottom feet. The infant showed cardiorespiratory distress and died at 10 hours. Necropsy revealed a ventricular septal defect but the brain was well developed and the optic nerves and tracts, olfactory nerves, corpus callosum, and septum pellucidum all appeared normal.

Secondary amenorrhoea and 47,XX,i(Xq) karyotype

A 25 year old female underwent normal pubertal development with menarche at 10 years of age. Her menses were regular until 21 years of age when they became scanty and irregular. She received cyclic hormonal therapy with withdrawal bleeding, but for 18 months before being seen

Necropsy findings in a child with FG syndrome

In 1983, Burn and Martin reported from this unit two male cousins with mental retardation, congenital hypotonia, intractable constipation, failure to thrive, and dysmorphic facies as possible examples of the X linked FG syndrome. Few pathological studies have been reported and we felt that it would be interesting to report the necropsy findings in the proband of Burn and Martin.

The brain. The brain weighed 800 g (normal for age 1100 g) and was brachycephalic. The convolutional pattern was simple with broader and fewer gyri than normal. A very large 'cystic' cavum septi pellucidi was present which communicated with the lateral and third ventricles through large fenestrations (figure). The corpus callosum was present throughout, but thin. Histologically, only acute anoxic changes and one isolated neuronal heterotopia in the cerebellar white matter were observed; no other evidence of migration defect was observed.

The septum pellucidum, which develops as a result of caudal growth of the corpus callosum, often shows a midline cleft-like space, called the cavum septi pellucidi, especially in fetuses and young children. Friede has suggested that a large cavum septi pellucidi may be a 'forme fruste' of agenesis of the corpus callosum and may be associated with a thin corpus callosum. This finding is therefore of interest, since case 2 reported by Opitz and
