Severe primary pulmonary hypoplasia (“acinar dysplasia”) in sibs: a genetically determined mesodermal defect?

We report on two sisters who died neonatally from severe pulmonary hypoplasia without obvious cause. It was not associated with any other pathological condition, except mild growth retardation. Histological examination of the lungs showed reduced alveolar parenchyma, with almost complete absence of mature alveoli. The amount of interstitial connective tissue was increased and the bronchial cartilage plates appeared dysplastic. The form of severe pulmonary hypoplasia is very unusual; so far only two similar cases have been reported as pulmonary “acinar dysplasia”. We present the first familial occurrence of this condition and suggest autosomal recessive inheritance.

Case 1 was the first child of a young, healthy, and non-consanguineous couple. She was born at 40 weeks after an uneventful pregnancy. Clinically, there was no oligo- or polyhydramnios and the mother experienced normal fetal movements. No maternal medication or exposure to potentially teratogenic agents were recorded. Immediately after birth, the infant developed severe respiratory distress. Chest x-rays and CT scans showed marked pulmonary hypoplasia, complicated by bilateral pneumothoraces. No other radiological abnormalities could be documented and the skeletal structures were normal. Despite intensive treatment, she died on the second day.

Clinical examination showed no external abnormalities. Body length (49.5 cm) and foot length (8.0 cm) were normal, but body weight (2860 g) and head circumference (32.5 cm) were between the 10th and 25th centile. The karyotype was normal.

The only gross abnormality found at necropsy was pulmonary hypoplasia (fig 1) with a combined lung weight of 20.2 g (normal 56±15) and a lung weight/body weight ratio of 0.007 (normal >0.012). The lungs were normally lobed, but the lobular markings were accentuated owing to thickened interlobular septa. Histology of the lungs showed extreme hypoplasia beyond the bronchial level with almost complete absence of mature alveoli and disproportionately numerous bronchi and bronchioli (fig 2). The bronchial branching pattern was normal. The peripheral lung parenchyma consisted merely of bronchiolmes and few immature canalicul structures, separated by an increased amount of interstitial connective tissue. The loosely textured and cellular interstitial tissue contained numerous, small, thin walled, and dilated blood vessels and foci of extramedullary haematopoiesis. The bronchial cartilage plates appeared unduly large and numerous and displayed a persistent immature cellular pattern. The alveolar cartilage and phrenic nerves were normal. The brain and spinal cord were normal both grossly and microscopically. Skeletal muscle biopsies showed no abnormalities.

Case 2 was born at 40 weeks as the product of the mother’s third pregnancy. A normal amount of amniotic fluid was documented clinically and confirmed by ultrasound. Her

Figure 1 Thoracic organs removed as a block. Severe pulmonary hypoplasia is illustrated by the fact that the inferior surfaces of the lungs are not in line with the apex of the heart.

Figure 2 The peripheral lung tissue contains virtually no alveoli, but consists merely of bronchiolmes. The bronchial cartilage plates are unusually prominent. Note the immature and cellular (“dysplastic”) aspect of the cartilaginous tissue (H&E).
second pregnancy ended with the birth of a healthy son. The third child died on the first day of life with respiratory distress. At autopsy, the lungs were of normal weight and radiological findings were exactly the same as in case 1. The combined lung weight was 18.9 g, with a lung weight/body weight ratio of 0.0067. The karyotype was normal.

Adenomatoid malformation of the lungs is a common cause of intractable neonatal respiratory distress. As a rule, pulmonary hypoplasia is not a primary malformation but a secondary deformation. Thus, the lung anlagen and initial organogenesis are normal, until a mechanical factor intervened, which thereafter proceeds abnormally. Secondary pulmonary hypoplasia is usually caused by one of the following conditions: prolonged oligohydramnios, diaphragmatic anomalies, skeletal dysplasia, massive chronic pleural effusions, or neuromuscular disease. Primary pulmonary hypoplasia, that is, an intrinsic abnormality of the lungs with poor development from the beginning, does exist but is exceedingly rare. It is a diagnosis of exclusion that can only be made after the known aetiology of secondary pulmonary hypoplasia has been ruled out. This needs thorough pathological examination, including examination of the central and peripheral nervous system and skeletal muscle tissue.

To date, only a limited number of cases of primary pulmonary hypoplasia have been reported, with both sporadic and familial occurrences. There is a striking lack of uniformity in the histology of these cases. Swischuk et al. and Langer and Kaufmann described reduced alveolar counts without other architectural abnormalities of the alveoli. Surprisingly, Frey et al. and Hamel found severely hypoplastic but histologically normal lungs with normal radial alveolar counts. In our two sibs, the lungs were severely hypoplastic and weighed less than 50% of the expected value for the gestational age. Histological examination showed an almost complete lack of alveolar development, increased amounts of interstitial connective tissue, and abnormal (dysplastic) bronchial cartilage. While, admittedly, primary pulmonary hypoplasia is a heterogeneous condition, the two cases reported here represent a specific entity. Similar histological findings have been described in only two previous, case, studies. We agree with Ruthledge and Jensen and Chambers that this lesion represents a severe form of peripheral pulmonary maldevelopment or "acinar dysplasia", rather than pure hypoplasia. Apparently, the lung development was arrested by means of canalicular pathology of the stage and development of the alveolar tissue did not take place. Stocker suggested that this form of pulmonary hypoplasia might be included in an expanded classification of cystic alveolar-malformation of the lung ("type 0").

The aetiology and pathogenesis of pulmonary acinar dysplasia are unknown. The epithelium of the respiratory tract up to the alveolar surface is a unique, multi-organ origin. Experimental embryological studies have shown that the segmental branching of the tracheobronchial tree is induced by the splanchnopleural mesoderm. This leads to the conclusion that acinar dysplasia may be an intrinsic defect of the lung mesoderm. The observation of increased interstitial connective tissue in hypoplastic fetal lungs in two cases appears to corroborate this. However, pulmonary development is an extremely complicated process, depending upon reciprocal epithelial-mesenchymal interactions. For instance, the developing pulmonary epithelium is the site of growth factors such as epidermal growth factor and transforming growth factor-α, which influence differentiation of the mesenchymal compartment and overall organogenesis. More specifically, defects in lung specific transcription factors, such as thyroid specific enhancer-binding protein, normally expressed in the developing pulmonary epithelium, have been shown to inhibit normal lung development, resulting in rudimentary cystic lungs. Thus, we cannot rule out a defect in the epithelial cell compartment as the initial cause of this malformation.

This is the first familial report of pulmonary acinar dysplasia, suggesting an autosomal recessive mode of inheritance for a gene critical for normal lung parenchymal development.

Coexistence of Gaucher disease type 1 and Joubert syndrome

Joubert syndrome (JS) is an autosomal recessive disorder in which cytogenetic, biochemical, and molecular markers are unknown. It is a distinct clinicopathological entity, characterised by cerebellar vermis dysgenesis, episodic tachypnoea and apnoea in the neonatal period, jerky eye movements, developmental delay, and hypotonia. Associated features may include agenesis of the corpus callosum, chorio-vascular colonization of the genitourinary system, and hepatic fibrosis, and polydactyly. The molecular basis of JS has recently been investigated by analysing the WNT1 gene, the human homologue of murine wnt-1, for mutations in patients with JS. It was concluded that WNT1 is not a critical gene for JS. In contrast to JS, the enzymatic and molecular basis in Gaucher disease (GD), an autosomal recessively transmitted lysosomal storage disorder, has been elucidated. GD is caused by a deficiency of glucocerebrosidase activity and the gene is located in chromosome 1q21. Clinically, there are three major variants of GD classified by the age of onset, severity of the visceral symptoms, and by the presence or absence of neurological involvement: type 1, the most common variant has a non-neuronopathic course; type 2 presents in infancy with severe neurological involvement; type 3 usually presents as a severe, slowly progressive neurodegenerative disease. Recently, new neonatal and fetal subtypes with a severe course have been described. In this human subtype and in murine models a total disruption of the glucocerebrosidase gene caused the fulminating disease. More than 50 different mutations in the glucocerebrosidase gene have been identified in patients with GD, producing an enzyme which is catalytically abnormal, rapidly degraded, or truncated. Although there is great variability in the severity of the disease in GD which cannot generally be explained by the genotype alone, the four most frequently identified mutations are to some degree predictive of the course of the disease. For example, patients having at least one N370S mutation, whether as homozygotes or compound heterozygotes, are at a very low risk for primary neurological involvement, while those who are homozygotes for the L444P mutation usually present with neurological abnormalities. In one hydrops fetus a
