**PRKAR1A**, one of the Carney complex genes, and its locus (17q22-24) are rarely altered in pituitary tumours outside the Carney complex

J Med Genet 2002; 39: e78

*The first two authors contributed equally to this work.

The tumour suppressor gene encoding the cAMP dependent protein kinase A (PKA) regulatory subunit α (Riα), PRKAR1A, has been mapped to chromosome 17q22-24 and is often mutated in the Carney complex (CNC),1–2 a multiple neoplasia and lentiginosis syndrome inherited in an autosomal dominant manner.1–4 The complex was first described as an association of lentigines, primary pigmented nodular adrenocortical disease (PPNAD), and a variety of endocrine and non-endocrine tumours (cardiac and breast myxomas).1–2 Growth hormone (GH) and prolactin (PRL) secretion abnormalities have been found in over two-thirds of patients with CNC1–7; in some cases, pituitary somatomammotrophic hyperplasia was also seen.7 GH producing adenomas (which also secrete small amounts of PRL) have been reported with increased frequency in patients with CNC; it was suggested that tumours in these patients develop in situ from precursor benign hyperplasia, following a sequence of genetic events not unlike the one described in other tissues.10–11

Genes implicated in cyclic nucleotide dependent signalling have long been considered likely candidates for pituitary tumorigenesis.10–11 Somatic activating mutations in the GNAS1 gene, which encodes the α subunit of the stimulatory G protein, lead to increased cAMP production and have been reported in approximately half of sporadic pituitary adenomas associated with acromegaly.14–16 In addition, methylation abnormalities of the GNAS1 gene are present in a significant number of pituitary tumours.17 Patients with McCune-Albright syndrome develop GH and PRL producing pituitary hyperplasia18–19 and their pituitary tissue harbours, as other affected tissues in these patients, somatic, activating mutations of the GNAS1 gene.18–20

In the present study, we investigated a large collection of sporadic pituitary adenomas (SPA) from the USA, UK, Japan, and France for loss of heterozygosity (LOH) of the 17q22-24 PRKAR1A locus and mutations of the PRKAR1A gene. In addition, six index cases that had presented with inherited pituitary tumours (4) or had MEN1-like symptomatology but negative family history (2), and had been screened and found negative for MEN1 mutations, were also screened for PRKAR1A mutations. No significant LOH and no PRKAR1A mutations were found in the sporadic tumours or the germline DNA of the patients with the MEN1-like manifestations.

**METHODS**

**Patients and DNA extraction**

The institutional review boards of the participating institutions approved the collection of the blood and tumour samples from the patients. None of the patients had CNC according to established criteria.21 DNA was extracted from blood and from frozen or paraffin embedded tumour samples by standard methods, as previously described.21

In total, we investigated 73 sporadic tumours, 20 of which had matching blood available for LOH analysis. These include 15 GH and 5 PRL secreting tumours (fig 1). All patients had presented with acromegaly or clinically significant hyperprolactinemia. For an additional collection of 53 tumour specimens, no blood DNA was available. Twenty-two of these tumours contained GNAS1 mutations, whereas all others were negative for mutations of this gene.

Six index cases who had been screened previously for MEN1 and were not found to have any germline MEN1 defects were also screened for PRKAR1A mutations. The first presented at the age of 23 years with amenorrhea and galactorrhoea owing to a PRL secreting adenoma; her sister had been diagnosed with a corticotrophin producing tumour. The second index case presented at the age of 19 years with acromegaly and a lipoma; his sister and daughter had prolactinoma and acromegaly, respectively. The third index case, the proband of a Brazilian family, presented at the age of 24 years with acromegaly; his brother and dead father also had acromegaly. The fourth index case presented at the age of 52 years with a pituitary macroadenoma that was not producing any hormone excess; his dead father had had surgery, too, at the age of 65 for a pituitary tumour. The remaining two patients presented at the ages of 26 and 75 years, respectively, both with somatomammatrophinoma and hyperparathyroidism and no other MEN1 related abnormalities or no known relative with endocrine tumours.

Microsatellite and loss of heterozygosity analysis

The polymorphic markers from 17q22-24 surrounding the PRKAR1A gene are listed in fig 1 in centromere to telomere order. The PRKAR1A [CA]n dinucleotide repeat marker is located in the 5' region of the PRKAR1A gene. Five pituitary tumours showed 17q LOH but in four the LOH zone was not continuous with the PRKAR1A gene.

Results

Loss of heterozygosity analysis for the 17q22-24 PRKAR1A locus

The location of the tested markers on 17q22-24 and corresponding LOH analysis is summarised in fig 1. There was no large deletion in any one specimen encompassing the whole gene, and there was no consistent deletion among specimens to suggest frequent deletion of part of the gene. One tumour (sample 11) showed LOH for the intragenic PRKAR1A marker but retained heterozygosity for D17S789 and two markers centromeric to it, whereas the subject was non-informative for the markers telomeric to the PRKAR1A gene. Interestingly, this tumour was an invasive, grade 3 somatotrophinoma that has been described elsewhere. Four additional tumours showed LOH for other markers in the PRKAR1A region, without, however, losing heterozygosity (sample 4) or producing any information for the PRKAR1A gene (sample 12).

Other microsatellite abnormalities, such as instability or size discrepancies, were not present.

PRKAR1A denaturing HPLC (DHPLC) analysis and sequencing

Heteroduplex (D-HPLC) of the PRKAR1A gene was performed in all samples with positive (DNA from CNC patients) and negative controls (DNA from previously screened patients) according to the conditions that we have established for PRKAR1A mutation detection by this technique (data not shown). Because of the lack of abnormalities, we decided to perform sequencing analysis of each PRKAR1A exon in all samples and in germline DNA from patients with inherited pituitary tumours (n=4) or MEN1-like manifestations (n=2). No PRKAR1A coding sequence mutations were found in any specimens.

Discussion

Pituitary tumours occur with increased frequency among patients with CNC. PRKAR1A, the gene mutated in almost half of the patients with CNC, codes for the most abundant regulatory subunit of cAMP dependent PKA, a cellular system highly involved in pituitary cell growth and function. In the present study, we investigated the hypothesis that LOH or alterations of PRKAR1A’s sequence are involved in sporadic pituitary tumours, as well as inherited, non-CNC related pituitary tumours. The results of the experiments described here suggested that the RI-α subunit of PKA is not a significant contributor to tumorigenesis in pituitary cells, as shown by infrequent LOH of the PRKAR1A 17q22-24 locus and lack of PRKAR1A mutations in a large international series of pituitary tumours. Although the number of families that was investigated was small, we may also conclude from this study that PRKAR1A mutations are not responsible for a significant number of non-CNC related inherited pituitary lesions. This observation follows the report of a large family with inherited acromegaly and lack of linkage to the 17q PRKAR1A locus. Additional studies on families with inherited pituitary tumours, however, need to be performed.

The pattern of a less frequent than expected involvement in sporadic lesions of a tumour suppressor gene that is responsible for a syndrome that predisposes to pituitary tumours is not unusual. MEN1, the gene mutated in MEN1, a syndrome
commonly associated with pituitary tumours and other lesions, is only infrequently mutated in sporadic pituitary tumours. Indeed, the tumours caused by germline mutations of tumour suppressor genes are often different from those sporadic lesions that are the result of somatic mutations of these genes.

It should be mentioned that methylation of the PRKAR1A gene is a possibility for gene inactivation in the few specimens that showed LOH. Methylation of genes in pituitary adenomas is only infrequently detected so far (Sandrini et al., unpublished data).

We conclude that PRKAR1A, a critical component of the PKA signalling pathway, does not appear to be frequently involved through mutation in the pathogenesis of pituitary tumours outside CNC.
