ABSTRACT

Background Adolescent idiopathic scoliosis exhibits high heritability and is one of the most common spinal deformities found in adolescent populations. However, little is known about the disease-causing genes in families with adolescent idiopathic scoliosis exhibiting Mendelian inheritance.

Objective The aim of this study was to identify the causative gene in a family with adolescent idiopathic scoliosis.

Methods Whole-exome sequencing was performed on this family to identify the candidate gene. Sanger sequencing was conducted to validate the candidate mutations and familial segregation. Real-time QPCR was used to measure the expression level of the possible causative gene.

Results We identified the mutation c.2645A>C (p. E882A) within the AKAP2 gene, which cosegregated with the adolescent idiopathic scoliosis phenotypes. AKAP2 is located in a previously reported linkage locus (IS4) on chromosome 9q31.2–q34.2 and has been implicated in skeletal development. The mutation was absent in dbSNP144, ESP6500 and 503 ethnicity-matched controls. Real-time QPCR revealed that the mRNA expression level in the patients was increased significantly compared with the family controls (p<0.0001).

Conclusions AKAP2 was therefore implicated as a novel gene mutated in a Chinese family with adolescent idiopathic scoliosis. Further studies should be conducted to validate the results from the perspective of both the genetics and pathogenesis of this disease.

INTRODUCTION

Adolescent idiopathic scoliosis (AIS) is a common, complex, three-dimensional spinal deformity that may occur from the age of 10 to skeletal maturity. The prevalence of AIS is 2%–4% in adolescents, with an obvious sex bias. The prevalence in females is higher than in males, especially in more severe cases.

In recent years, several aetiological factors have been associated with AIS, such as hormonal disturbances, developmental neuromuscular dysfunction (paraspinal muscle) and so on. Nevertheless, no factor has been convincingly shown to be an actual aetiological factor for AIS. Several studies have noted familial clustering of AIS, autosomal-dominant and X-linked of inheritance have been observed. Therefore, AIS is widely accepted to be a disease for which hereditary or genetic factors likely play key roles.

Many genetic studies regarding AIS have previously been reported. Family-based linkage analyses have revealed several AIS linkage loci, such as 19p13.3 (IS1), 17p11.2 (IS2), 8q12 (IS3), 9q31–q34 (IS4) and 17q25-qter (IS5). However, only the POC5 gene has been identified as causing idiopathic scoliosis. Moreover, SNPs in GPR126, CHL1 and LBX1 genes and so on have been documented to be associated with AIS risk. However, only polymorphisms near the LBX1 gene have successively been replicated in different ethnic groups. All these findings suggest that AIS is a disease with high genetic heterogeneity.

In this study, we identified a mutation within the AKAP2 gene that cosegregated with the phenotypes of a Chinese AIS family with an autosomal-dominant inheritance using whole-exome sequencing.

MATERIALS AND METHODS

Subjects and clinical examinations

An AIS family from the Chinese Han population participated in our study. Ten subjects (five affected) were recruited and underwent detailed clinical examinations. All members of the family were ascertained and examined by two experienced orthopaedic surgeons. Diagnostic criteria of AIS were determined through history and physical examinations, including a complete neurological examination and standing anteroposterior/lateral X-ray films of the entire spine. AIS is defined as a lateral curvature of the spine greater than 10° with vertebral rotation and no congenital deformity. Peripheral blood from all members were collected after signing informed consent. In addition, 503 ethnicity-matched subjects were enrolled as controls. This study was approved by the institutional review board of the State Key Laboratory of Medical Genetics.

Whole-exome sequencing and analysis

Peripheral blood lymphocytes were collected for all of the recruited family members. Genomic DNA was extracted using the standard phenol–chloroform method. Three individuals, including two affected cases (IV10, IV11) and one family control (II16), were selected for whole-exome sequencing. Approximately 1 μg of DNA from each sample was used to construct an exome library using the SureSelectXT Target Enrichment System for Illumina Paired-End Sequencing Library kit from Agilent Technologies (Santa Clara, California, USA), following the manufacturer’s instructions.

An Illumina Solexa GAIIx sequencer was used to sequence the prepared library using a paired-end 76 bp×2 method according to the manufacturer’s instructions.

The generated bcl files were converted to fastq files using the configureBcToFastq function of the Illumina CASAVA programme (Illumina, San Diego, California, USA), and this step included a basic evaluation of the sequencing quality. We then used the FastQC (v0.10.0) tool to evaluate the quality of the reads and our in-house script to filter low-quality reads. The quality-passed reads were subsequently mapped to the human reference sequence (GRCh38/hg38) using the alignment tool Burrows–Wheeler Aligner (v0.6.2). After removing duplicate aligned reads using SAMTools and recalibrating base quality scores using the Genome Analysis Toolkit (GATK), single nucleotide variations (SNVs) and short insertions and deletions (indels) were then identified using the GATK package and annotated by ANNOVAR. We included variations shared by affected cases that were not present in the control and with a read depth ≥8× and Phred score quality ≥30 for further analysis.

**Sanger sequencing**

The candidate mutation identified from whole-exome sequencing was confirmed via Sanger sequencing; segregation patterns were obtained to determine whether the variant cosegregated with the scoliosis phenotype in the pedigree. Then, the variant that segregated with the clinical phenotype was screened in 503 ethnicity-matched normal controls to determine the allele frequency. PCR primers were designed using the Primer3 program. All variants identified were validated by independent PCR amplification and DNA bidirectional sequencing performed on an ABI 3130 DNA analyser.

**RNA extraction and real-time QPCR**

Total RNA was isolated from Epstein–Barr virus-transformed B cell lines using the RNeasy Plus mini kit (Qiagen, Hilden, Germany). cDNA was synthesised from a total of 2 μg of RNA using the RevertAid First Strand cDNA Synthesis Kit (Thermo Scientific, Waltham, Massachusetts, USA) and oligo (dT) primers. Reactions were carried out in a CFX96 Touch Real-Time PCR Detection System (Bio-Rad Laboratories, Hercules, California, USA) using Maxima SYBR Green qPCR Master Mix (Thermo Scientific, Waltham, Massachusetts, USA). The data were analysed using Bio-Rad CFX Manager Software. The mRNA expression levels of AKAP2 were analysed with one pair of primers, and the amplified products covered the location of the mutation. Expression levels were normalised to beta-actin (ACTB). Specific primers for each gene were as follows: AKAP2 (forward primer, 5′-AGCTTGAGCCCTGACTTAGC; reverse primer, 5′-CATTCTCTGGGCTTTTAG; product 117 bp) and ACTB (forward primer, 5′-CACGATGGAGGGGCCGGACTCATC; reverse primer, 5′-TAAAGACCTCTATGCCAACACAGT; product 366 bp). Each assay was performed in five independent tests. The data were analysed by unpaired two-tailed t tests using GraphPad Prism V5 software (V5.0).

**RESULTS**

**Clinical characterisations**

Patients distributed over four generations exhibited an autosomal-dominant mode of inheritance of AIS (figure 1A). Notably, the female members were predominantly affected, that is, there was a sex bias (four females vs one male), and females presented with a more severe phenotype than males. The proband with a 62° Cobb angle main curve underwent a corrective operation for AIS in a Chinese teaching hospital in 2006.
By taking a careful family history, the pedigree with AIS was determined. Five individuals (II5, III7, IV9, IV10 and IV11) in this pedigree were diagnosed with AIS (figure 2). The 503 controls were ethnically matched with the patients and skeletally mature at the time of the study. Individuals with any potential evidence of skeletal diseases, metabolic disorders,
growth anomalies or other diseases known to affect normal skeletal metabolism were excluded.

A segregating mutation was identified in AKAP2

We generated an average of 10 Gbp of sequences with more than 77X coverage for each subject. More than 97% of the targeted bases were covered to identify SNVs and indels (see online supplementary table S1). Finally, we identified 22 370 coding variants including 11 128 non-synonymous SNVs, splicing SNVs and indels for IV10; 23 605 coding variants including 11 195 non-synonymous SNVs, splicing SNVs and indels for IV10; and 22 428 coding variants including 11 098 non-synonymous SNVs, splicing SNVs and indels for IV11 (table 1).

No variant in POC5 was found in our exome sequencing data. We used the following steps to filter the variants: (1) exclude high frequency SNPs (minor allele frequency (MAF)>0.01) in the 1000 genome (2015 Aug), and ESP6500 (version esp6500siv2) and ExAC (version ExAC03) databases; (2) exclude homozygous variants; (3) extract the segregating variants in the exome sequencing of individuals; (4) exclude variants in 236 in-house controls; and (5) extract variants in the reported linkage intervals (table 1, see online supplementary table S2). After this filtering analysis, three variants in MDGA1(6p21.2), AKAP2(9q31.3) and C17orf75 (17q11.2) genes remained for further analysis (table 1). Subsequently, Sanger sequencing demonstrated that only one variant within AKAP2 (chr9:112810878-112934791, ENST00000434623), c.2645A>C (p.E882A), cosegregated with the phenotype in all of the family members (figure 1A, B). We also conducted segregation analyses of the variants located outside of the reported linkage regions. No other variant segregated with the AIS phenotypes in this family. This mutation was absent in the 503 population-matched normal controls and the dbSNP144 and 1000 population-matched normal controls. Functional and conservation analysis revealed that this variant is deleterious and highly conserved. The QPCR analysis showed that the expression level of mutated AKAP2 was increased significantly compared with the four controls, indicating the consequence of this mutation.

The AKAP2 gene encodes A-kinase (PRKA) anchor protein 2, which interacts with the regulatory RII subunits of protein kinase A (PKA). The AKAP2 protein most likely participates in forming polarity in signalling pathways or in constructing PKA–RII effector complexes that capture, amplify and focus diffuse transcellular cAMP signalling systems. This gene belongs to the AKAP family and two controls outside the family. The expression level of family control (III:3) is regarded as ‘1 for normalisation. The results revealed that the level of AKAP2 mRNA expression was increased significantly compared with the controls (p<0.0001) (figure 1D).

**DISCUSSION**

This research identified a novel variant, c.2645A>C (p.E882A), within the AKAP2 gene that segregated with the phenotypes in the pedigree. This mutation was absent from the 6500 the National Heart, Lung, and Blood Institute (NHLBI) exome data, 1000 genomes, dbSNP144 and 503 population-matched normal controls. Functional and conservation analysis revealed that this variant is deleterious and highly conserved. The QPCR analysis showed that the expression level of mutated AKAP2 was increased significantly compared with the four controls, indicating the consequence of this mutation.

The AKAP2 gene encodes A-kinase (PRKA) anchor protein 2, which interacts with the regulatory RII subunits of protein kinase A (PKA). The AKAP2 protein most likely participates in forming polarity in signalling pathways or in constructing PKA–RII effector complexes that capture, amplify and focus diffuse transcellular cAMP signalling systems. This gene belongs to the AKAP family and two controls outside the family. The expression level of family control (III:3) is regarded as ‘1 for normalisation. The results revealed that the level of AKAP2 mRNA expression was increased significantly compared with the controls (p<0.0001) (figure 1D).

view the consequence of this mutation.
Several lines of evidence support the pathogenicity of the mutation. AKAP2 on 9q31.3 was precisely mapped to a previously reported AIS locus (IS4) on chromosome 9q31.2–q34.2. Ocaka et al.21 studied a large family of British descent with autosomal dominant (AD) AIS. In this family, the proband bore a scoliotic curve of 56° determined by the Cobb method before corrective surgery, with the curvature in other affected family members ranging from 15° to 65°. The author performed a genome-wide linkage analysis in the family and obtained a maximum lod score of Zmax = 3.64 (θ = 0.0) at marker D9S2157. Haplotype analysis identified a 21 Mb critical interval on chromosome 9q31.2–q34.2. Seven additional families showed cosegregation of the disease with marker D9S2157, and among all of the families, individuals with the disorder existed in each generation without skipping generations. Both males and females were affected, and in seven families, male-to-male transmission appeared eight times. Therefore, transmission of AIS is compatible with an AD inheritance pattern. The family we studied has much in common with these families, such as the observation of multigenerational disease, the observation of members affected with an AD mode of AIS, and the observation of affected subjects with a more severe spinal curvature.

The AKAP2 gene was previously reported to be interrupted by a translocation in a case with Kallmann syndrome and bone anomalies.20 The patient had a kyphotic deformity, flatfoot with the absence of the fifth toe bilaterally, eversion of the foot, abnormal fusion of the scaphoid with the astragalus bone and dysplasia of the hip. To explore how AKAP2 contributes to the disorder, the author detected mAkap2 expression in mouse embryos by in situ hybridisation studies. A high level of expression in cartilaginous structures of the embryo was observed, in correspondence with the phenotype of the proband carrying the translocation in this study. These studies revealed that Akap2 contributes to the development of cartilage. The abnormal response of growth plate chondrocytes to the action of melatonin in both proliferation and development of cartilage. The abnormal response of growth plate chondrocytes to the action of melatonin was observed, in correspondence with the phenotype of the embryo was observed, in correspondence with the phenotype of the proband carrying the translocation in this study. These studies revealed that Akap2 contributes to the development of cartilage.

In conclusion, our study first indicated AKAP2 as a novel gene mutated in the AIS family by combining exome sequencing with segregation analysis, conservation analysis and expression analysis. Further cell functional studies and animal studies of AKAP2 will be indispensable to interpret its role in the aetopathogenesis of AIS.
