SUMMARY Two children with monosomy 10p13 are reported. In the first case the monosomy was the result of a maternal balanced translocation $t(3;10)(p27;p13)$ while the second case was a de novo mutation. We reviewed clinical details of cases reported so far and found that certain symptoms are typical of the deletion of a comparatively large segment of chromosome 10 short arms. These symptoms include mental and growth retardation, skull abnormalities, antimongoloid slant of the eyes, ear abnormalities, anteverted nostrils, abnormalities of the hands and feet, cryptorchidism in boys, and, primarily, hypoplasia or aplasia of the olfactory bulbs and olfactory tracts as well as narrow palpebral fissures or eyelid ptosis.

Since the first description by Elliott *et al*¹ of a probable partial deletion of 10p in a child with many clinical symptoms, a number of reports of patients with 10p partial monosomy have been published,²⁻⁷ thus enlarging the clinical picture.

Deletion of part of the chromosome 10 short arms associated with deletion of the long arm terminal segment is also found in cases with ring chromosome 10.⁸⁻¹² As a rule, the deletion of both telomeric segments is small and the clinical picture is not as severe as in cases of the above mentioned 10p partial monosomy.

Defined chromosome abnormalities, particularly monosomies, are suitable material for human genome mapping. Two enzyme loci have been thought to be located on 10p, namely red blood cell hexokinase (HK₁) and pyrophosphatase (inorganic) (PF).^{13,14}

Case reports

FAMILY A (FIG 1)

The proband comes from a rural family of low intelligence who were reluctant to cooperate. The first (illegitimate) child (III.9) was born 10 days preterm in 1969. Birthweight was 2750 g and head circumference was 34.5 cm. The infant had dysmorphic features including quadricephalic skull, low set and abnormally shaped ears, and aphony with normally formed epiglottis and normal larynx. A bifid uvula was also found. The eyes had an antimongoloid slant and there was micrognathia and anteverted nostrils. In addition, bilateral inguinal

FIG 1 Pedigrees of the families with partial monosomy 10p.

hernia and cryptorchidism were found. Cytogenetic examination in the pre-banding era revealed an apparently normal male karyotype. The infant died suddenly at the age of 3 months. The second child (III.10), a boy with partial trisomy of chromosome 10 short arms, was born in 1971. He showed retarded speech development at the age of 10 and minute cerebral motor defects, but development was normal and there were no dysmorphic features.

Case 1 (III.13)

This was the fifth child of the family. Delivery occurred 2 weeks before term. Birthweight was 2760 g, length was 47 cm, and head circumference was 34 cm. During the postnatal period a very soft cry and trouble in sucking were noted. Examination

at the clinic during the first month of life showed a dysmorphic syndrome with the following signs: quadricephalic skull with prominent forehead, broad skull sutures, abnormally shaped low set ears rotated backwards, flat nose bridge, anteverted nostrils, high palate, hypertelorism, ptosis, more pronounced on the left side, the forefinger crossing over the middle finger, and cryptorchidism. The infant's cry was soft and purring. Neurological examination showed overall muscular hypotonia as well as weak sucking and gripping reflexes. Abduction of the hips was limited. Congenital hypothyroidism was also found. Repeated EEG examinations showed normal findings although epileptiform spasms were observed from the 8th to the 18th week of age. At the age of 14 months amblyopia associated with divergent strabismus was noted. Psychomotor development has been greatly retarded since the first examination.

Examination at the age of 4 years showed a clinical picture dominated by marked psychomotor and growth retardation. The child could not walk, contact was very poor, and no signs of speech were present. The mask-like face showed extremely

limited mobility and a constantly open mouth: he frequently ground his teeth. The skull was flattened at the sides and the face was asymmetrical. Ptosis was more prominent on the right side. Mild hypertelorism, divergent strabismus, and a beak-like nose with a flattened tip were observed. The alveolar arch of the maxilla was prominent and the teeth were abnormally formed. The chin slanted backwards, the ears were not fully formed and were small, rotated backwards, and very low set (fig 2a). The hair-line was low at the nape of the neck. Red blood cell hexokinase determinations gave normal values. Cytogenetic examination showed a karyotype of 46,XY,del(10)(p13) (fig 3b).

FAMILY B (FIG 1)

The proband (case 2, II.2) was the third child of a 28-year-old mother and 36-year-old father. Delivery occurred 2 weeks after term. Birth weight was 2800 g, length was 48 cm, and head circumference was 35 cm. Clinical examination revealed the following (fig 2b): hypertelorism, abnormally shaped low set large ears, rotated backwards, anteverted nostrils, micrognathia, short and thick neck, syndactyly of fingers 3 and 4, clinodactyly, transverse creases on both palms, hypospadias, and cryptorchidism. Cardiological examination showed a developmental heart defect. The child had to be fed through a tube because of sucking difficulties. Despite intensive cardiac therapy, the congenital heart defect led to acute heart and respiratory failure, resulting in the death of the child on the 17th day of life. Cytogenetic examination revealed a terminal deletion in the chromosome 10 short arms with a break in band 10p13 (fig 3c).

Discussion

Stene and Stengel-Rutkowski¹⁵ analysed 11 families with familial translocations involving a segment of the short arm of chromosome 10, resulting in partial trisomy 10p. However monosomy of the chromosome 10 short arms was not found in any member of the families. All six cases reported so far of partial monosomy 10p,²⁻⁷ as well as our second case, have arisen de novo. In contrast, all four segregation possibilities, including a child with partial monosomy 10p, were found in our first family, that is, the children of a mother carrying a balanced translocation t(3;10). In this family, in addition to one child with a normal karyotype (fig 1) and one with the same balanced translocation as his mother, a third child, a boy, had trisomy of the distal segment of chromosome 10 short arms with severe clinical symptoms. The first child had a phenotype similar to that of his monosomic sib; thus he may have been carrying a

chromosome anomaly of the monosomy type, although trisomy cannot be excluded. The marked similarity of the clinical picture to that of his monosomic sib (quadricephalic head, weak cry, and sucking problems) and the presence of features like antimongoloid slant of the eyes and anteverted nostrils that do not occur in trisomy 10p¹⁶ would favour monosomy.

The fact that there are many more cases of trisomy 10p than monosomy 10p confirms the view that monosomy of a part of the genome usually results in more serious defects than trisomy of the same part. Most monosomic cases are probably eliminated in early embryonal life.

In the few reports of partial monosomy 10p, monosomy of the p13→pter segment has been observed most frequently.^{2-4,7} The case reported by Prieto *et al*⁵ concerned an interstitial deletion limited to the segment 10p13; in the case of Fryns *et al*⁶ a terminal deletion 10(p14→pter) was observed. Both our cases of monosomy of the segment 10(p13→pter) confirm this to be the most frequent type of monosomy 10p seen. This may indicate a predominance of breakpoints in band p13.

Owing to the limited number of observations (table) it is difficult to draw more general conclusions concerning the phenotypic features of 10p partial monosomy, since the symptoms are very variable and also frequently overlap with other chromosome abnormalities. Probably growth retardation associated with mental retardation in older children are the main signs. Antimongoloid slant of the eyes, associated with ptosis or narrow palpebral fissures or both, is typical to a certain extent. Abnormalities of the face, like hypertelorism, broad nose bridge, a peculiar shape to the nose, and anteverted nostrils are very frequent, the same being true for ear abnormalities, epicanthic folds, micrognathia, abnormalities of the hands and feet, and cardiac and urinary tract malformations. Cryptorchidism was noted in boys in four out of five cases. Four out of nine children died within the first 3 months of life. The frequent ophthalmological symptoms, including fundus anomalies, microphthalmia, astigmatism, and cataract, are noteworthy. In all three children so far examined post mortem, hypoplasia (once) or aplasia (twice) of the olfactory bulbs and tracts was observed. Hyperactive behaviour was found in two out of five living children.

For comparison, the lower half of the table summarises the phenotypic signs of five reported patients with a ring chromosome 10. Apart from some non-specific symptoms, signs occurring in pure partial deletions of 10p can also be seen. This is true

for retardation in growth (five cases), widely spaced nipples (four cases), and strabismus (three cases), in addition to other symptoms. Again, one case showed hyperactive behaviour. Narrow palpebral fissures or ptosis were not present in any of the cases. It should, however, be pointed out that these signs are not usually observed until a certain age has been reached and of the 14 patients reported, six died in early childhood.

Based on the data in the table and on an analysis of the clinical symptoms, association of phenotypic signs with deletion of certain chromosome segments may be suspected. In deletions of the more proximal segments 10p13 and 10p14, hypoplasia or aplasia of the olfactory bulbs and olfactory tracts, as well as narrow palpebral fissures or ptosis or both, have been observed in addition to a number of other relatively frequent symptoms. These signs have not been reported in cases of terminal deletion (ring chromosome). In contrast, strabismus and widely spaced nipples may be seen in patients with deletion of the terminal segment of 10p as well as a larger part of 10p; this suggests a possible association of these symptoms with deletion of the terminal segment of 10p.
