Holoprosencephaly and polydactyly: a possible expression of the hydroletharus syndrome

H Bachman, R D Clark, W Salahi

Abstract

We report two fetuses with hydrocephalus, features of holoprosencephaly, and postaxial polydactyly born to a consanguineous Mexican-American couple. The phenotype is consistent with the hydroletharus syndrome, although holoprosencephaly has not previously been seen in this condition. We believe other similar cases with a trisomy 13 phenotype but normal chromosomes may also have the hydroletharus syndrome.

In 1981, Salonen *et al*¹ first described a lethal malformation syndrome in 28 Finnish newborns, which they called hydroletharus. Named for the key features of hydramnios, hydrocephalus, and lethality, hydroletharus is an autosomal recessive condition also associated with polydactyly, micrognathia, microphthalmia, congenital heart defect, and abnormalities of the respiratory system. In 1987, Anyane-Yeboa *et al*² delineated the condition further, noting midline brain abnormalities.

We describe two sibs from a consanguineous union who had many of the features of hydroletharus and holoprosencephaly.

Case report

At 15 weeks' gestation, a 29 year old G4,P2,TAB1 Mexican woman with two normal daughters sought medical attention for a fever of 40°C owing to pyelonephritis. A routine fetal ultrasound was done which showed an omphalocele, hydrocephalus, hypotelorism, and microphthalmia. An amniocentesis

indicated a 46,XY normal male karyotype and normal amniotic α fetoprotein. The pregnancy was electively terminated at 18 weeks' gestation. On examination of the fetus, cebocephaly, bilateral microphthalmia, omphalocele, and postaxial polydactyly of the left hand and foot were noted (fig 1). Trachea and bronchi, lobulation of the lungs, and the heart were normal. There was no dorsal cleft through the occiput, and the shape of the foramen magnum was normal. The frontal bone was missing. The brain showed holoprosencephaly of the lobar type. There was a large common ventricle and the dorsal thalamus and basal ganglia were dysplastic, fused into a midline mass on the posterior inferior ventricular wall. In addition, there was agenesis of the olfactory nerves, optic nerves, oculomotor nerves, corpus callosum, septum pellucidum, hippocampal formation, and the descending tracts, including the corticospinal tract. The cerebellum was severely hypoplastic and there was dysplasia of the midbrain, pons, and inferior olivary nuclei. Microscopic examination of the cerebral cortex showed the usual trilaminar pattern of immaturity, and the cerebellar cortex was normal.

Revised version accepted for publication 7 June 1989.

Figure 1 Postmortem view of case 1 showing single nostril, omphalocele, postaxial polydactyly of left hand and foot, and splayed, broad hallux.

Figure 2 Postmortem view of case 2 showing microphthalmia and premaxillary agenesis causing the midline facial defect.

It was discovered that a previous pregnancy had been electively terminated by prostaglandin induction at 20 weeks after hydrocephalus was seen on ultrasound. A necropsy of this male fetus showed premaxillary agenesis, microphthalmia, hydrocephalus, and postaxial polydactyly of the hands and left foot (fig 2). The brain showed micropolygyria and an incomplete Sylvian fissure bilaterally with total absence of the aqueduct of Sylvius. In addition, cranial nerves I and II, the corpus callosum, and descending tracts including the corticospinal tract were absent. The midbrain, pons, and inferior olivary nuclei were dysplastic. Chromosome studies were not performed.

The family history is remarkable because the parents are third cousins. There are no other affected relatives, although our patient reports that she had a sister who died at a few days of age with a large head. No records are available for this child who was born in Mexico.

Discussion

We believe that our patients have the hydroletharus syndrome, as they exhibit almost all of its features: hydrocephalus, midline structural defects of the brain, microphthalmia, omphalocele, and postaxial polydactyly. Our patients did not have defects of the heart or lung. The absence of polyhydramnios may not be valid in our cases because both pregnancies were terminated by 20 weeks' gestation. The most

common abnormality in the feet, duplication of the hallux, was lacking; however, our patients did have large, deviated big toes. Finally, the consanguinity in this family supports such an autosomal recessive trait.

Although holoprosencephaly has not specifically been described as a feature of hydroletharus, in their initial report Salonen *et al*¹ described the absence of midline brain structures in eight of 28 cases. The most detailed description of absent midline brain structures was provided in a case report by Anyane-Yeboah *et al*.² In that case, gyral patterns were abnormal and olfactory bulbs, tracts, and the anterior commissure were absent. The thalami were fused and mammillary bodies could not be identified. Aughton and Cassidy³ described a mild case of hydroletharus with an absent septum pellucidum and a partial posterior defect in the corpus callosum. Krassikoff *et al*⁴ reported a patient with hydroletharus in whom massive hydrocephalus and holoprosencephaly were noted prenatally by ultrasound. At necropsy, in addition to bilateral postaxial polydactyly of the hands, the most striking feature was a large midline facial defect with absent nasal bone and cartilages and midline cleft lip and palate. The pituitary, corpus callosum, and septum pellucidum were also absent. The lateral ventricles communicated via the subdural space, which resulted in the appearance of holoprosencephaly noted on ultrasound. Thus, although holoprosencephaly in itself is not stressed, absence of midline brain structures is well documented in the hydroletharus syndrome.

Similar patients, resembling a trisomy 13 phenotype with holoprosencephaly and postaxial polydactyly may also represent hydroletharus. In 1987, Young and Madders⁵ reported a previously undescribed syndrome of holoprosencephaly, heart defects, and postaxial polydactyly with normal chromosomes. That stillborn male had premaxillary agenesis with bilateral microphthalmia, postaxial polydactyly of the hands, alobar holoprosencephaly with absence of midline structures, pachygyria, and a ventricular and atrial septal defect. The following year Moerman and Fryns⁶ reported a stillborn female with normal chromosomes and similar findings: holoprosencephaly with alobar hydrocephalus, bilateral postaxial polydactyly, neocerebellar hypoplasia, and microphthalmia with retinal dysplasia. The authors considered hydroletharus in their differential diagnosis, but discounted it in part because of the holoprosencephaly. In addition, Shiota and Tanimura⁷ described a six week male embryo with holoprosencephaly with absence of midline structures, cardiac defects, and bilateral postaxial polydactyly in both arms and legs. Although chromosomes were not analysed, it is possible that this embryo had the same syndrome.

Holoprosencephaly, in which the embryonic forebrain fails to cleave sagittally and transversely, can be

caused by chromosome abnormalities, teratogens, and many single gene disorders. Cohen,⁸ in his largest and most recent review of holoprosencephaly, lists seven autosomal recessive syndromes that have holoprosencephaly as a feature. Hydroletharus is not specifically mentioned, although the cases of Young and Madders⁵ and Shiota and Tanimura⁷ are listed as 'pseudotrisomy 13 syndrome of unknown genesis'.

We propose that holoprosencephaly is a feature of the hydroletharus syndrome. Furthermore, the diagnosis of 'pseudotrisomy 13 syndrome' in the case of Young and Madders⁵ and other reported cases of holoprosencephaly and postaxial polydactyly should be reconsidered. These cases may also represent hydroletharus. Finally, hydroletharus should be considered in the differential diagnosis of any case of holoprosencephaly with other anomalies.
