Abstract

The breakpoints of seven interstitial deletions of the long arm of chromosome 16 and two ring chromosomes of this chromosome were mapped by in situ hybridisation or by analysis of mouse/human somatic cell hybrids containing the deleted chromosome 16. Use of a high resolution cytogenetic based physical map of chromosome 16 enabled breakpoints to be assigned to an average resolution of at least 1.6 Mb.

In general, interstitial deletions involving q12 or q22.1 have broadly similar phenotypes though there are differences in specific abnormalities. Deletions involving regions more distal, from 16q22.1 to 16q24.1, were associated with relatively mild dysmorphism. One region of the long arm, q24.2 to q24.3, was not involved in any deletion, either in this study or in any previous report. Presumably, monosomy for this region is lethal. In contrast, patients with deletions of 16q21 have a normal phenotype. These results are consistent with the proposed distribution of genes, frequent in telomeric Giesma light band regions but infrequent in G positive bands.

(*J Med Genet* 1993;30:828-32)

Complete or partial aneuploidy for a chromosome is often associated with a specific pattern of recognisable malformations. Although such aneuploidy may involve large regions of DNA which would contain many genes, it is apparent that aneuploidy syndromes can originate from the effects of abnormal dosage of relatively few genes. For example, Down's syndrome is usually associated with an extra chromosome 21 but variants exist which are trisomic for only a small portion of this chromosome. Use of these cytogenetic variants has allowed the dissection of the Down phenotype into individual features, each localised to a specific region of the chromosome, with such features likely to be the result of imbalance of one or few genes.¹

Autosomal chromosome monosomies are lethal. However, partial monosomies, often originating as meiotic segregants from parental balanced translocations, can be viable and be associated with a specific recognisable pattern of malformations. Common examples are the Wolf-Hirschhorn syndrome associated with del(4)(p16.3) and cri du chat syndrome associ-

ated with del(5)(p15.3). As for partial and full trisomies, it is likely that one or a few genes are involved in producing the abnormal phenotype.

Aneuploidy for the entire chromosome 16 is lethal. Trisomy 16 is found in approximately 5% of spontaneous abortuses. This trisomy has a lethal effect early in pregnancy with the average gestational age being approximately 10 weeks, and a blighted ovum most frequently observed, although occasional embryos up to 10 mm long have been described.² Monosomy for this chromosome has not been reported in studies of abortion material, although karyotyping of sperm shows that this aneuploidy probably occurs.³

To our knowledge, there have been no confirmed partial monosomies for the very distal segment of the long arm of chromosome 16. A patient reported as a del(16)(q22)⁴ was subsequently shown to be a balanced t(5;16) translocation.⁵ A malformed newborn with a karyotype 46,XX, del(16)(q21) was reported in 1977.⁶ However, the quality of chromosome banding available at that time was probably not sufficient to establish the exact nature of this deletion. Monosomy for this region of the chromosome might be expected to be generated from the meiotic segregation of translocations with breakpoints in this region but no cases have been reported to our knowledge. In contrast, a number of patients with interstitial long arm deletions of chromosome 16 have been reported. Some of these patients have similar patterns of malformations and this has resulted in the concept of a deletion syndrome involving the long arm of chromosome 16. However, the identification of a critical region for this deletion syndrome has been ambiguous, with both 16q12-13^{7,8} and 16q22.1⁹ being suggested as critical.

In this study, a high resolution cytogenetic based physical map of chromosome 16 has been used to enable detailed localisation of the long arm breakpoints of seven chromosome 16q interstitial deletions and two ring chromosomes.

Materials and methods

CELL LINES

The origin of the seven interstitial deletions and two ring chromosomes 16 is given in table 1. Four of the cell lines were fused with the mouse cell line A9 and mouse/human somatic cell hybrids isolated containing the deleted

chromosome 16 in the absence of the normal 16.¹⁷

MOLECULAR MAPPING OF BREAKPOINTS

The long arm breakpoints of the interstitial deletions and of the ring chromosomes were mapped in relation to the high resolution cytogenetic based physical map of chromosome 16 by three different procedures. For four deletions the availability of somatic cell hybrids allowed mapping of the deletions by Southern blot or PCR analysis of the hybrid cell DNA.¹⁷ Breakpoints of the remaining cell lines were localised by mapping DNA markers by fluorescence in situ hybridisation (FISH) to metaphase spreads as previously described.¹⁸ A DNA marker was considered to be outside of the deletion when signal was seen on both the deleted and normal chromosomes. A DNA marker was scored as being within the deletion if there was signal observed on only one chro-

The breakpoints of ID1 and ID3–ID5 were mapped by Southern blot or PCR analysis of mouse/human somatic cell hybrids containing the deleted chromosome.¹⁷ The presence (+) or absence (–) of a DNA marker on the chromosome 16 with a deletion was determined by FISH except in cases indicated by an asterisk where this was determined by inheritance of polymorphic (AC)n microsatellite markers. The order of DNA markers is from centromere to qter.

mosome 16 in at least 10 metaphases. DNA markers were all previously mapped to the high resolution cytogenetic physical map of chromosome 16.¹⁷
The third method of mapping the extent of a deletion was by typing DNA from the proband and parents with polymorphic microsatellite (AC)n repeats. When the proband showed loss of a parental allele this indicated that the locus was contained within the deletion.

CLINICAL DETAILS

The clinical details of some of the patients have been previously reported (table 1).
Patient ID4. Delivery of this girl was at 34 weeks' gestation by caesarian section performed because of polyhydramnios and fetal distress. Birth weight was 1950 g (10th to 50th centile), length 45 cm (50th centile), and head circumference 30 cm (10th centile). The dysmorphic features are summarised in table 3 and include brachycephaly, cleft palate, pulmonary atresia with hypoplastic right ventricle and tricuspid valve, limited extension of finger joints, especially the distal interphalangeal joints, and proximally placed thumbs. Subsequent development was poor with failure to thrive and death at 74 days. There was no necropsy.
Patient ID6. Delivery of this girl was at term by caesarian section because of fetal decelerations. Her birth weight was 2890 g. She was intubated in the delivery room with meconium below her vocal chords but she did not develop respiratory distress and was discharged at 5 days in good health. At 6 months decreased growth was noted and at 12 months she was referred for evaluation of developmental delay. At this time physical evaluation

Figure 1 Photograph of patient ID7.

showed head circumference and height at the 25th centile for age and weight at the 3rd centile for age. She had a flat occiput and right epicanthic fold but otherwise was not dysmorphic. Re-examination at 7½ years showed a short, microcephalic girl with minor dysmorphism consisting of recessed hairline, slightly prominent broad forehead, supernumerary nipple (present in her normal mother), short and broad big toes, and small nails on the fifth toes. She was retarded, not toilet trained, and had general learning difficulties.

Patient ID7. This female was delivered spontaneously at 37 weeks' gestation. Birth weight was 3170 g (50th to 75th centile),

length 48 cm (50th centile), and head circumference 34 cm (75th centile). During the first few months there was normal feeding and development. At 8 weeks, clinical examination showed trembling, hypertonia, narrow palpebral fissures with antimongoloid slant, broad nasal root, flat forehead, an extremely large anterior fontanelle, long philtrum, high arched palate, and evidence of micrognathia. The two lower incisors were present at birth (both lost spontaneously at 4 weeks), the ears were low set and dysmorphic, there were flexion defects of the middle fingers, and widely spaced nipples. A photograph of the patient is presented in fig 1.

Figure 2 Ideogram of the long arm of chromosome 16 showing location of deletions. The hybrid breakpoints are designated by the prefix 'CY'. The extent of deletions is indicated by the dotted lines on the right of the ideogram. The two fragile sites, FRA16B and FRA16D, provide physical links of the panel to the chromosome at the interface of bands 16q21 and q22.1 and at band 16q23.1 respectively. The breakpoints between CY8 and FRA16B, FRA16B to FRA16D, and FRA16D to the telomere are distributed evenly within each of these intervals. The location of the breakpoints of deletions ID1, ID3, ID4, and ID5 has been determined by analysis of the corresponding mouse human somatic cell hybrids CY138, CY130, CY127, and CY125 respectively. These data have been previously published.¹⁷

Results

The results of mapping DNA markers to the interstitial deletions of 16q and the two ring chromosomes 16 are given in table 2 and presented diagrammatically in fig 2. In two instances (ID1, ID2 and ID5, ID6) the breakpoints of the deletions mapped to the same region. Mapping of additional DNA markers would be required to resolve whether within these regions there is overlap or separation of the breakpoints. The two ring chromosomes retained APRT and therefore must be broken distal to this gene. Overall, deletions of the long arm of chromosome 16 are associated with a viable phenotype and these deletions can include regions of the entire long arm except the distal tip from q24.2 to q24.3. There is the possibility of a small region of non-overlap between ID1 and ID2, and between ID5 and ID6.

A summary of the clinical details of these patients is given in table 3. The deletion ID3 was associated with a normal phenotype. The girl with the deletion ID6 was developmentally delayed but had few dysmorphic features. There was considerable overlap present in the pattern of abnormalities seen in the other patients even though different regions of chromosome 16 were involved. These abnormalities were often relatively non-specific, and can be attributed to generalised disruption of development. More specific abnormalities are the association of ID1 with sensorineural deafness

and ID4 and ID5 with abnormalities of the cranial sutures and heart defects. The deletions ID2, ID6, and ID7 were not associated with any distinctive malformations.

The deletion of ID4 is completely contained within ID5 and the clinical features of the two patients were similar. The patient with the ID5 deletion had all the major features of ID4, but with additional features of gastrointestinal abnormalities, renal abnormalities, and malformations of the feet. It is tempting to attribute these additional abnormalities to the extra genes which are presumably deleted at the distal overlap of ID4 and ID5.

The malformations of the two ring chromosomes will not be discussed since a deletion of the short arm of chromosome 16 is also present (unpublished data).

Discussion

A number of patients with interstitial deletions of the long arm of chromosome 16 have been reported.^{7-9 13 19-23} There is obvious similarity in the pattern of malformations in different patients and this has resulted in the concept of a deletion syndrome. However, the region involved has been disputed with 16q12.2-q13^{7,20} and 16q22⁹ being contenders for the critical region that, when deleted, is associated with this syndrome. There are five deletions in the region from q12 to q22.1. The deletion ID3 segregates in three members of a two generation pedigree without phenotypic effect,¹² thus eliminating this region in any clinical phenotype. Deletions ID1 and ID2 are non-overlapping in the region from q12.1 to q13 while ID4 and ID5 are overlapping deletions in q22.1. Although there are many similarities between the clinical features of these patients there are differences. The patient with the ID1 deletion has sensorineural deafness, patients with ID4 and ID5 have abnormalities of the cranial sutures and heart defects, while the patient with the ID2 deletion did not have any distinctive malformations. The ID5 deletion was shown to extend further distally than the ID4 deletion. It could be considered that in the patient with the ID5 deletion the additional clinical abnormalities of the gastrointestinal tract, renal system, and feet could be attributed to genes deleted in this extra segment.

It is evident that analysis of the breakpoints of interstitial deletions of chromosome 16 by classical cytogenetics does not have sufficient resolution to provide meaningful correlations between the bands deleted and the phenotype. These deletions can be mapped by either molecular cytogenetic analysis using FISH, molecular characterisation of somatic cell hybrids containing the deleted chromosome, or by analysis of polymorphic microsatellite repeats. The availability of a high resolution cytogenetic based physical map of DNA markers where localisation is at an average resolution of at least 1.6 Mb provides the basis for the sequential selection of DNA markers for rapid localisation of breakpoints. By mapping breakpoints using these procedures there can be

meaningful correlations between the extent of deletions and a patient's phenotype.

The seven interstitial deletions and two ring chromosomes provide evidence that, with the exception of 16q24.2 to q24.3 for which there have been no reported cases, deletions for any region of chromosome 16q can be associated with a viable phenotype. It is suggested that the region q24.2 to q24.3 may be lethal when monosomic since there are no reports known to the authors of unbalanced segregants from translocations which are monosomic for this region. The one example of a deletion encompassing this region was reported when, historically, banding was of low resolution,⁶ and therefore this karyotype cannot be confirmed. It is hoped that further high resolution mapping of rearrangements in this region of chromosome 16 will allow further delineation of this region.

There are now several reports of patients with deletions involving Giesma dark bands who have normal phenotypes. These are 16q21 (deletion ID3 in this report), 13q21,²⁴ 5p14,²⁵ and 11p12.²⁶ These results support the concept that dark G bands are late replicating, AT rich, and with a paucity of genes.²⁷ In contrast, the apparent lethality of deletions of the 16q24 region are consistent with the concept of a high concentration of genes in the telomeric light G bands.²⁸

We thank Sinoula Apostolou for preparing fig 2 and Norman Doggett for supplying cosmid probes on chromosome 16. We would like to thank Dr Bernhardt and the parents of patients who have generously cooperated with this study. DFC and GRS acknowledge support from the United States Department of Energy (Grant No DE-FG02-89ER60863) and the Australian National Health and Medical Research Council.
