First trimester prenatal diagnosis of Menkes disease by DNA analysis

Zeynep Tümer, Tønne Tønnesen, Johann Böhmman, Wolfgang Marg, Nina Horn

Abstract

Menkes disease is an X linked recessive disorder of copper metabolism characterised by neurological symptoms and connective tissue manifestations. The defective gene in Menkes disease has recently been isolated and the gene product is predicted to be a copper transporting ATPase. The diagnosis of Menkes disease has hitherto been performed by biochemical analysis, based on intracellular accumulation of copper. Cloning the gene opened up the possibility of establishing precise and reliable carrier and prenatal diagnosis by defining the molecular defect. In this report we describe the partial deletion of the Menkes gene in a patient who had inherited the mutation from his phenotypically normal mother. This information enabled us to perform prenatal diagnosis by direct mutation analysis of the mother's sixth pregnancy and we detected the same deletion, indicating that the male fetus was affected. This first prenatal diagnosis of Menkes disease by direct mutation analysis shows some advantages of DNA analysis compared to biochemical diagnosis.

(J Med Genet 1994;31:615-617)

Menkes disease is an X linked recessive disturbance of copper metabolism mainly characterised by peculiar hair, connective tissue manifestations, and progressive psychomotor retardation, leading to death in early childhood. Most of the clinical symptoms can be explained by malfunction of one or more of the known copper requiring enzymes, indicating deficiency of an intracellular copper transport protein.¹ The Menkes locus has been mapped to Xq13.3² and the gene defective in Menkes disease has recently been isolated by three different groups including ours.³⁻⁵ On the basis of nucleotide sequences the protein is predicted to encode a copper transporting ATPase and the 5' end contains six putative metal binding sites, supporting the copper transport defect in Menkes disease.

To date the only definitive diagnosis of Menkes disease has been by biochemical analysis, based on intracellular accumulation of copper owing to impaired outflow. Prenatal diagnosis in the first trimester has been performed by measuring copper in chorionic villi, a test very susceptible to exogenous copper contamination. Carrier diagnosis by measuring ⁶⁴Cu uptake in cultured fibroblasts is possible, but not reliable in all cases owing to

random inactivation of one of the X chromosomes. Furthermore, biochemical analysis is only performed in a few centres in the world. To establish a means of precise, easy, and reliable carrier and prenatal diagnosis as well as to determine the genotype-phenotype correlation, we started defining the lesions disrupting the gene in about 230 Menkes patients referred to our institute since 1977.

So far we have identified deletions and duplications/insertions of different sizes and localisations disrupting the Menkes gene in 40 unrelated patients⁴ (unpublished data) with Southern blot hybridisations using cDNA and genomic probes.⁴ In 75% of these patients we detected an altered band pattern, which could be used in determining the carrier status.⁶ In these cases we investigate all the available female family members for possible carrier status, to be able to perform a subsequent prenatal diagnosis by DNA methods.

In this report we describe the genetic lesion in a Menkes family, where we performed the first prenatal diagnosis by direct mutation analysis, and show some advantages of DNA analysis compared to biochemical diagnosis.

Materials and methods

CLINICAL REPORT AND FAMILY HISTORY

The index patient was the first child of unrelated healthy parents. He had typical clinical features of Menkes disease including psychomotor retardation, muscular hypotonia, feeding difficulties, dry and loose skin, and abnormal hair. Tonic-clonic seizures began at the age of 4 months and could not be controlled with antiepileptic therapy. EEG showed multifocal seizure activity and on nuclear magnetic resonance scan slight cerebral atrophy and distension of the inner cerebral cavities were observed. Low levels of serum copper (2.1 µmol/l, n=11-25) and caeruloplasmin (0.11 g/l, n=0.15-0.60) and increased ⁶⁴Cu uptake in cultured fibroblasts (60.6 ng ⁶⁴Cu/mg protein/20 hours, control range 7.4-25.0) confirmed the clinical diagnosis. Cu-histidine and penicillamine treatment was not effective and the child died at the age of 17 months from pneumonia. Cytogenetic analysis did not show any visible deletion of chromosome material. ⁶⁴Cu uptake values of the phenotypically normal mother were higher than normal (51.2 ng ⁶⁴Cu/mg protein/20 hours, control range 11.1-26.7) indicating that she was a carrier.

In the mother's second pregnancy, copper studies on chorionic villi (18.1 ng copper/mg ww, controls (n=50) 0.3-1.2) indicated an affected male fetus. The copper content of chorionic villi taken at termination was, however, normal (1.25 ng copper/ng ww) and

copper uptake into cultured fetal fibroblasts gave conflicting results leaving the final diagnosis unresolved.

In her third pregnancy prenatal diagnosis by measuring copper in chorionic villi also indicated an affected male fetus (7.5 ng copper/mg ww) and the pregnancy was terminated. The prenatal diagnosis was confirmed by measuring the copper content in kidney from the formalin fixed fetus (6.44 ng copper/mg ww, control range 0.52–1.9). Following these pregnancies the mother gave birth to two phenotypically normal girls.

The mother had four sisters and six brothers. Two sisters have one healthy son each and three brothers have died in early infancy without a diagnosis.

DNA ANALYSIS

Genomic DNA was prepared from chorionic villi or cultured fibroblasts. *Hind*III or *Eco*RI digested DNA fragments were separated through a 0.7% agarose gel, Southern blotted, and analysed by hybridising⁷ with genomic (0.35 kb 1–1) or cDNA (1.4 kb cMNK1 and 0.35 kb cMNK3) probes (fig 1). The cDNA probes are overlapping and they represent at least five exons in the 5' putative metal binding end of the Menkes gene.⁴ cDNA probes together with the more distal genomic probe (1–1) detect a genomic region of 48 kb representing at least eight exons (unpublished results) (fig 1).

Measurement of ⁶⁴Cu uptake in cultured fibroblasts and copper content in chorionic villi were performed as previously described.⁸

Results and discussion

The diagnosis of Menkes disease was established clinically and biochemically in the first child of the family, and following the isolation of the Menkes gene we could describe the underlying molecular defect. DNA analysis of the proband showed a partial deletion in the 5' metal binding end of the Menkes gene (fig 1). When the cDNA probe cMNK3 was hybridised against the *Eco*RI and *Hind*III digests of the patient's DNA, all the normal bands were shown to be deleted (results not

shown). The cDNA probe cMNK1 detected an altered sized band, instead of the normal band, with *Hind*III digests (fig 2). The genomic probe 1–1 also detected an abnormal fragment instead of the normal one with *Eco*RI digests (results not shown). By detecting the junction fragments at both ends, we could confine the deletion to an approximately 25 kb genomic fragment. According to our unpublished results, this fragment represents five exons and four putative metal binding sites at the 5' end of the gene (fig 1). DNA analysis of the mother confirmed her carrier status, indicated by an altered sized band in addition to a normal band representing the normal X chromosome. These findings enabled us to perform prenatal diagnosis in her present (sixth) pregnancy by means of DNA analysis in parallel with the biochemical analysis. The presence of the same mutation indicated that the male fetus was affected and the family decided to terminate the pregnancy. The high copper value in chorionic villi (6.5 ng copper/mg ww) was in concordance with this result. The diagnosis was confirmed after termination of the pregnancy by a high placental copper value and increased copper incorporation in cultured fetal fibroblasts.

This study illustrates some advantages of DNA analysis compared to biochemical analysis, which has hitherto been the only definitive diagnostic test. Biochemical diagnosis of Menkes disease is based on intracellular accumulation of copper owing to impaired outflow. First trimester prenatal diagnosis is carried out by measuring copper in chorionic villi. As the normal copper content in this tissue is very low (1 ng copper per mg tissue), the test is highly susceptible to exogenous copper contamination, which could easily produce false positive results. The whole procedure of chorionic villi sampling must therefore be absolutely free of copper contamination, but as the samples are normally processed locally at the time of sampling, though rare,

Figure 1 Organisation of the 5' end of the Menkes gene and the spectrum of the molecular defect in the family. JF=junction fragment. Black boxes indicate exons.

Figure 2 Southern blot analysis. The DNA was digested with *Hind*III and hybridised with the cDNA probe cMNK1. The approximately 23 kb junction fragment (indicated by arrow) can be seen both in the proband (II.1), the present (sixth) pregnancy (II.3), and the carrier mother (I), who also shows the 10 kb normal band, representing the normal X chromosome. The male fetus of her second terminated pregnancy (II.2), shows a normal band pattern, indicating that he was not affected. This analysis also shows clearly that chorionic villi (II.2, II.3) were not contaminated by maternal tissue. C=control.

this condition is not always fulfilled, so that in such cases DNA analysis becomes especially important. When the separation of maternal tissue from the chorionic villi is not optimal, this may also be a source of false positive or false negative results in biochemical analysis. DNA analysis is therefore very useful in determining the presence of maternal tissue (fig 2). In the mother's second pregnancy the contradictory results could not be explained by exogenous copper contamination or ineffective separation of the maternal deciduum. The copper follow up studies did not clarify the diagnosis, but the DNA studies allowed a decisive diagnosis and showed that the aborted male fetus was normal. Introduction of DNA analysis will therefore be beneficial especially in first trimester diagnosis of Menkes disease. Since 1983, 116 first trimester prenatal diagnoses in male fetuses at risk have been carried out at The John F Kennedy Institute using copper analyses. Even though the overall accuracy of diagnosis by biochemical studies is 98 to 99%, there have been 16 problematical cases, where DNA analysis would have been of great value (manuscript in preparation).

Until now biochemical tests for pre- and postnatal and carrier diagnoses of Menkes disease could only be accomplished in a few laboratories in the world. DNA based analysis will thus allow the diagnosis of Menkes disease to be made in any laboratory with DNA analysing facilities.

In the present case, ^{64}Cu uptake value of the mother was within the previously described range for female Menkes carriers,⁹ and the molecular analysis confirmed her carrier status. As copper uptake analysis depends on gene expression and may not be informative for carrier diagnosis owing to random X inactivation, molecular analysis will provide the means of a more precise and reliable carrier diagnosis.⁶

Three maternal uncles of the index patient died in early infancy without a diagnosis, suggesting that they might have been affected. As

the mother's carrier status has now been determined, it is likely that this partial deletion of the Menkes gene in one of her X chromosomes was inherited from her mother. This knowledge opens up the possibility of investigating other female members of the family for carrier status.

The role of molecular genetic approaches in diagnostic medicine have been increasing rapidly in recent years. By providing means of a reliable and precise carrier and prenatal diagnosis of Menkes disease, DNA analysis will benefit both clinicians and families. Establishment of the exon-intron structure of the Menkes gene will enable a PCR based analysis which will also accelerate the diagnosis.

We acknowledge Drs Anthony P Monaco and Jamel Chelly for collaboration in cloning the Menkes gene, which made this study possible. Karen Friis-Henriksen and Annie Levin Larsen are thanked for their technical assistance. ZT is supported by Fellowship 42-2901 from the Danish Research Academy.
