The Baller-Gerold syndrome

L. Van Maldergem, A Verloes, L. Lejeune, Y. Gillerot

Abstract
A case of severe craniosynostosis-radial aplasia (Baller-Gerold) syndrome is described in a newborn male, following a pregnancy complicated by polyhydramnios and intrauterine growth retardation. Death occurred after two hours owing to a prolonged apnoeic spell. Extensive agenesis of the frontal and parietal bones, resulting in a very large fontanelle, in addition to coronal bilateral craniosynostosis was observed at necropsy. There was also bilateral radial agenesis, oligodactyly of the hands and feet, a midline facial angiomata, and a scrotally positioned anus, all of which have been described in some of the 10 previously reported cases. Microcephaly, erythroblastosis of the liver, and pancreatic islet cell hypertrophy were also noted.

Syndromes with the association of craniosynostosis and multiple congenital abnormalities are numerous. There are also more than 50 syndromes including radial agenesis. However, there is only one rare syndrome with the association of craniosynostosis and radial agenesis, namely the Baller-Gerold syndrome. We present here a new case of this unusual syndrome.

Case report
The parents were Caucasian, aged 24 and 22 years, and were probably related since their grandmothers, bearing the same name, originated from the same small village and called each other 'cousin'. The pregnancy was uneventful until 7 months of gestation when intrauterine growth retardation (IUGR) was first detected on echography. Fetal weight calculated from abdominal measurement and femur length decreased from the 50th to the 3rd centile. At 8 months, major malformations of the cranial vault could be seen. The limbs could not be visualised clearly because of the lack of amniotic fluid owing to advanced gestational age. Diabetes mellitus screening tests were negative. Birth occurred at 37 weeks with breech presentation. The baby weighed 2250 g, length 43 cm, and head circumference 35 cm. Apgar score were 10 and 7 at one and five minutes. A severe malformation complex was obvious and included the following: turriccephaly, short neck, shortening of the upper limbs, club hands and feet, and oligodactyly (fig 1). The baby became rapidly hypotonic, then cyanotic, and died despite attempts at resuscitation. Necropsy was performed four hours after death. The facial appearance was striking because of marked turriccephaly, a large forehead, midfacial hypoplasia with a small nose covered by a midline angiomata, antverted nostrils, long upper lip where the angiomata expanded, a very small mouth with a thin vermilion border, high arched palate without cleft, and slight retrognathia (fig 2). The ears were low set and posteriorly rotated. There was a partial agenesis of the cranial vault with the fontanelle wide open from the occiput to the supraorbital ridges (fig 3). Moderate micropropolygyria of the deformed brain was noted. The neck was short and the nipples widely spaced. There was clinically evident bilateral radial agenesis and absence of the thumbs with shortening of the distal and middle phalanges. The anus was anteriorly placed at the posterior limit of the scrotum (fig 4). No cardiac abnormality was found. Microscopically, there was a slight overdevelopment of the endocrine pancreas. Otherwise, histological examination of all other organs was unremarkable. Karyotype was 46,XY (G and R banding) on peripheral lymphocytes and cultured skin fibroblasts.

Discussion
The Baller-Gerold syndrome, an autosomal recessive craniosynostosis complex associated with agenesis or severe hypoplasia of the radius, has been previously described 12 times.1-10 The phenotype has been outlined in a recent review by Cohen11 and includes growth deficiency, sudden infant death syndrome (neonatal death occurred in our case), a peculiar facial appearance with malformed (5/11)
and low set (2/11) ears, prominent nasal bridge (3/11), epicanthus (3/11), a midline capillary haemangioma (3/9), and micrognathia (2/12), all of which were present in our case apart from epicanthus. Other occasionally (3/12) described facial features (cleft palate, bifid uvula, high arched palate, and prominent mandible) were absent. Other systems involved were cardiac (VSD, patent ductus arteriosus, supra-valvular aortic stenosis), renal (ectopia), anal (imperforate anus, anterior position, perineal fistula), and skeletal (joint limitations, rib fusion and flat vertebrae, absent middle phalanx). It is worth noting that cardiac malformations were absent in our patient but the midline angiomata and the anteriorly displaced anus were present. In addition, together with severe craniosynostosis, a lack of coalescence of the cranial bones resulted in what have been called 'large fontanelles' in previously reported cases but was, in our case, virtually agenesis of the largest part of the cranial vault. The probable consanguinity of the parents reinforces evidence for autosomal recessive inheritance in the Baller-Gerold syndrome.

The necropsy findings were non-specific except for moderate polymicrogyria, which has also been mentioned in one of the three necropsy cases reported so far. Abundant extra-medullary erythropoiesis, as seen in fetomaterial incompatibility, was present in the liver in one case, but does not provide any explanation for the sudden death which has been recorded in three cases out of 12. The hypertrophy of the islets of Langerhans is also interesting in that it raises the question of a possible hypoglycaemic attack soon after birth. One interesting point stated in the case of Huson et al is the premature separation of the centromeres observed on cytogenetic analysis, pointing to a possible overlap between Baller-Gerold and Roberts SC-phocomelia syndromes. This was not present in our case. However, C banding, which is the method of choice to express this anomaly, was not performed in our case.

In conclusion, this case report confirms the Baller-Gerold or craniosynostosis-radial aplasia syndrome as a recognisable multiple congenital anomaly syndrome and further delineates the facial appearance and associated malformations. It brings the number of perinatal deaths to four out of 12, thus suggesting lethality, possibly linked to impairment of glucose homeostasis. Further studies are required, particularly insulin assessment and glucose tolerance tests, to investigate this hypothesis. Prenatal diagnosis rests on echographic detection of cranial and limb malformations during the second trimester.
