Two sibs with cleft palate, ankyloblepharon, alveolar synechiae, and ectodermal defects: a new recessive syndrome?

A Seres-Santamaria, J L Arimany, F Muñiz

Abstract

Hay and Wells in 1976 reported seven patients from four families who had an inherited condition of which the main features were ankyloblepharon, ectodermal defects, and cleft lip and palate. The inheritance pattern was determined to be autosomal dominant. This condition is known as AEC syndrome or Hay-Wells syndrome.

We report a family with two sibs showing some of these features and congenital adhesions between the upper and lower jaws (alveolar synechiae). There seems to be a recessive pattern of inheritance as neither of the parents has any features of the syndrome. This could be described as a recessive form of Hay-Wells syndrome with additional features or be named as a new syndrome.

Case report

A family with two affected sibs is reported. The parents are unrelated; neither parent nor any other member of the family has any ectodermal defect or other trait suggesting one of these syndromes. The parents are healthy and non-consanguineous. The mother is slightly short. There were no previous pregnancies.

Case 1

Case 1, an 11 year 7 month old girl, was the product of a term pregnancy with a normal labour and spontaneous vaginal delivery; her birth weight was 2700 g (between the 3rd and 10th centiles). Soon after birth it was observed that her eyelids were fused. She also had synechiae of the upper and lower gums and from these to the inner side of the cheeks, she had a cleft uvula, and her nails were dystrophic.

The eye bands were released surgically and the oral synechiae were removed to allow normal feeding.

She has shown normal physical and mental development; her weight is above the 97th centile and her height on the 90th. She has had no major problems and her intelligence is normal.

Physical examination at 11 years 1 month showed a well developed, pubertal girl with mild obesity, cleft uvula, some small synechiae involving the gums and the buccal epithelium, pits in the lower lips, onychodystrophy (fingernails and toenails), and coarse hair. The skin was normal, there were no sweating problems, and the teeth were normal.
Discussion

The Hay-Wells syndrome is characterised by congenital filiform fusion of the eyelids, ectodermal defects, cleft lip/palate, and an autosomal dominant inheritance pattern. Two of the most distinctive, although not unique, findings in Hay-Wells syndrome are the tendency to scalp folliculitis and the ankyloblepharon filiform adnatum. Some features seen occasionally in patients with Hay-Wells syndrome include deafness, lacrimal duct atresia or obstruction, supernumerary nipples, and syndactyly.4

Ankyloblepharon has also been seen in other forms of ectodermal dysplasia, such as in curly hair–ankyloblepharon–nail dysplasia (CHANDS)5 and Roselli-Guilenetti syndrome,6 but in the first there is no oral cleft, and the second has as the most distinctive features popliteal and perineal pterygia and genital anomalies.4

The ectodermal defects in Hay-Wells syndrome can be partial or complete hair loss, coarse, wiry hair, absent or dystrophic nails, pointed, widely spaced teeth, and partial anhidrosis.

Clefting of the palate has been present in nearly all reported patients, but cleft lip is a variable feature.4 In some cases there is mental retardation.8

The family we report has two affected sibs, a boy and a girl, who have some of the features of Hay-Wells syndrome (table), but they have alveolar synechiae and the inheritance pattern seems to be autosomal recessive as neither of the parents has any ectodermal defect or other trait suggesting one of these syndromes.

Our patients show some similarities to the child reported by Obishi et al.,8 born to consanguineous parents, with ankyloblepharon, alveolar synechiae, commissural lip pits, hypoplastic nails, and woolly scalp hair, but the child had no cleft uvula/palate as in our patients.

The family we document could be described as having an autosomal recessive variant of Hay-Wells syndrome or, perhaps more likely, having a new syndrome of oral clefting with alveolar synechiae, ankyloblepharon, and ectodermal defects as the main features.
