Male infertility as the only presenting sign of cystic fibrosis when homozygous for the mild mutation R117H

Since the identification of the cystic fibrosis gene (CFTR),1 more than 265 mutations have been described (CF Genetic Analysis Consortium, 1992). The most common disease causing mutation, ΔF508, occurs in approximately 70% of CF chromosomes and causes moderate to severe disease,2 with variable prevalence in populations of different ethnic origins. Among the numerous rare mutations, R117H (a G to A transition at nucleotide 482) produces a missense amino acid substitution (arginine to histidine) in the first transmembrane domain of CFTR. It has only been reported in the heterozygous state, usually with ΔF508 occurring in the other CFTR gene; the compound heterozygotes are mildly affected.3

We have studied a 30 year old French male with sterility owing to congenital bilateral absence of the vas deferens (CBVAD). He is homozygous for the R117H CFTR mutation, which was detected by DGGE screening and characterised by direct sequencing of PCR amplified DNA from blood using the Sequenase 2.0 kit. The subject has no respiratory or pancreatic involvement and has a normal sweat electrolyte value. His parents are not consanguineous and there are no other cases of CBVAD or CF in his family.

Based on the primary finding of a higher rate of AF508 heterozygosity in infertile males,1,4 it has recently been suggested that isolated CBVAD might represent a primary genetic form of CF.5,6 Several males presenting with infertility have been found to be heterozygotes for AF508 and other known mutations and on investigation have mild CF with normal or raised sweat electrolytes and subclinical lung disease. However, this is the first report of homozygosity for R117H. It results in a clinical presentation of CBVAD cystic fibrosis completely devoid of the classical symptoms of CF.

Among the reported cases of rare alleles of CFTR found in compound heterozygotes, the R117H mutation seems to be highly represented. It should be systematically screened for in all patients with CBVAD, as it may represent a common CF mutation causing very mild disease, with infertility as the only clinical presentation.

Limb/pelvis/uterus-hypoplasia/aplasia syndrome

I read with great interest the recent papers of Farag et al from Kuwait and Camera et al from Italy reporting additional patients similar to those we described in 1985 as a new autosomal recessive syndrome.1 This brings the number of cases with limb/pelvis-hypoplasia/aplasia syndrome (LPHAS) to nine (five female and four male). This total includes one case from Brazil2 and the three siblings from Israel.3 Among these five sibships, the three sets of parents were first cousins or double first cousins.4 I was delighted to see these reports because they provided further support (in my belief) that the private syndrome does not exist. Often many 'new' syndromes are referred to as 'private' particularly if they are first described in the third world. So called 'private' syndromes may in fact be previously unrecognised or unreported and yet be 'relatively common' in certain populations. The absence of known parental consanguinity in two families with LPHAS could imply that the gene frequency in the relevant population may not be very low.

I wish to report further data on one of the original patients who was re-evaluated at the age of 18 (in 1990) because of absent menarche. Her perinatal and other sexual characteristics had developed by the age of 15 years. She and her parents were not particularly anxious about her fertility because of her severe handicap. They wanted to be sure that there were no life threatening consequences of the disease. Her FSH, LH, and prolactin levels were normal. Ultrasonography showed apparently normal ovaries and absent uterus. This was confirmed by another ultrasonographer. It was not possible to perform pelvic examinations because of virginity. Laparoscopic examination was declined.

These data indicate normal gonadal development in a female and support the finding of Farag et al of uterus hypoplasia/aplasia. Such findings in two out of five reported females suggest that it is not fortuitous and is probably a variable manifestation of LPHAS that should be considered in future cases.

From a nosological perspective, LPHAS is an appropriate descriptive designation. However, in the light of the müllerian hypoplasia/aplasia, the term limb/pelvis/uterus-hypoplasia/aplasia may be a more precise name. Three of the Camera reports have used the respective authors' names for syndrome identification.1,2 To avoid confusion, I suggest the use of the name of the first reporting author followed by a brief description of the major components. Considering the expansion in the number of new reported syndromes, this policy would make for easier cataloguing of genetic disorders.

Molecular characterisation of β thalassaemia heterozygotes in Brazil

At present over 100 different molecular defects producing thalassaemia have been identified. However, a limited number of specific mutations predominates in a given population.1 Most carriers of β thalassaemia in Brazil are descendants of Italian immigrants among whom the prevalence of β thalassaemia trait has been estimated as 6-4%. We have collected a total of 130 of which has been not been completely investigated,2 we carried out a study to determine the β globin mutations in patients heterozygous for β thalassaemia in south eastern Brazil.

High molecular weight DNA was prepared from peripheral leucocytes of 70 unrelated thalassaemia heterozygotes from the region of Campinas in south eastern Brazil (São Paulo State). The diagnosis was based on red cell indices and quantitation of haemoglobin A and F as previously described.3 Identification of the β thalassaemia mutations was made by hybridising PCR amplified DNA with 32P labelled synthetic oligonucleotide probes. The primers for amplification, the sequence of the probes, and the dot blot hybridisation procedures were as previously described.4 Probes for four mutations were used: a) BS1-nt 110 (G→A), BS1-nt 6 (T→C), and BS1-nt 1 (G→A). The presence or absence of BS1-nt 275 (C→G) mutation was confirmed by digestion of the amplified DNA with RalI. For this reaction we used a pair of primers which amplified a fragment from BS1-nt 264 to codon 132 of exon 6 of the β globin gene.

Hybridisation of amplified DNA from the samples with the four oligonucleotide probes allowed the characterisation of all 70 samples (97.1%) β thalassaemia chromosomes. The distribution and frequencies of the mutations are listed in the table. The mutation BS1-nt 1 (G→A) is not observed among the patients. From our
