Isolated sacral agenesis in a fetus monosomic for 7q36.1→qter

Abstract
A fetus with severe sacral agenesis and intrauterine growth retardation, ascertained at prenatal diagnosis, was found to be carrying an unbalanced form of a paternal balanced reciprocal translocation (7;19)(q36.1;q13.43), resulting in functional monosomy for 7q36.1→qter. Necropsy confirmed that the fetus had isolated sacral agenesis type II. A critical region for autosomal dominant sacral agenesis has recently been mapped to the 7q36 region. This case provides further evidence for a sacral agenesis locus in this region and may help to refine the critical region further.

Keywords: sacral agenesis; 7q36

Sacral agenesis is a rare, usually sporadic disorder in which there is failure of development at the caudal end of the neural tube, resulting in aplastic malformations of the sacral vertebrae.1 Sporadic sacral agenesis is most commonly associated with maternal diabetes,2 3 and the rarer, hereditary form may occur in isolation or as part of the Currarino triad of anorectal, sacral, and presacral anomalies.4 The association of terminal 7q deletions with developmental anomalies of both the sacral region and the prosencephalon has been well documented.5 6 A critical region for holoprosencephaly (HPE), an early malformation of the rostral end of the neural tube resulting in structural anomalies of the forebrain and midface, maps to chromosomal region 7q36,7 and a gene for autosomal dominant sacral agenesis has recently been reported to map to the same region.8

Case report
A 29 year old Portuguese woman, G1, P0, was referred for amniocentesis at 16 weeks' gestation because of a raised maternal serum alphafetoprotein. Ultrasound studies detected intrauterine growth retardation and a possible sacral anomaly. On the basis of the cytogenetic result (see below) the pregnancy was terminated, and necropsy showed a female fetus with features of intrauterine growth retardation and severe sacral hypoplasia (sacral agenesis type II) (fig 1), but no internal congenital abnor-

Isolated sacral agenesis in a fetus monosomic for 7q36.1→qter

Cytogenetic and FISH studies
All cells examined from cultured amniocytes had an apparent small terminal deletion of one chromosome 7 which, on examination of the parental karyotypes, was shown to be the unbalanced product of a balanced 7;19 translocation (fig 2). Further examination revealed that a number of cells were not karyotypically normal. The placenta showed extensive areas of infarction. There was no consanguinity and the mother was not diabetic.

Discussion
Adjacent 1 segregation of the balanced paternal 7;19 translocation had given rise to a fetus which was trisomic for a small portion of distal 19q (q13.43→qter) and monosomic for the subtelomeric region of 7q (q36.1→qter). Duplications of distal 19q have been reviewed by Boyd et al.9 but none of the clinical features described in the review was present in our case, presumably because the duplicated regions in the reviewed cases were more extensive than in the present case. By contrast, the association between terminal 7q deletions and developmental anomalies of the prosencephalon and the caudal region is well known and has been reviewed by Morichon-Delvallez et al.6 Three of the 13 cases described in that paper showed coexistence of HPE and sacral agenesis. Lynch et al. proposed that the genes for HPE and sacral agenesis are allelic, and involvement of different functional domains of the gene could explain the occurrence of one or other of the phenotypes. The phenotypic features of HPE and sacral agenesis are variable, with features of HPE ranging from midface hypoplasia to cyclopia,7 and those of sacral agenesis from partial agenesis of the coccyx to complete absence of the sacral and lumbar vertebrae.1 Lynch et al. proposed that this variable expression, and early miscarriage particularly involving the more severe phenotypes, may obscure the true frequency of the coexistence of the two defects. Sacral agenesis has also been reported in combination with spina bifida, a classical neural tube defect.10 Grav et al.11 in an abstract, described three cases with deletions of distal 7q with variable phenotypes. Case 1, monosomic for 7q34→qter, showed no evidence of HPE; case 2, hemizygous for the D7S427 probe in 7q36, had a single central incisor, a feature seen in the mildest expression of HPE; and case 3, monosomic for 7q36→qter, had HPE which was detected prenatally by ultrasound. These variable HPE phenotypes, together with the coexistence of sacral agenesis, HPE, and spina bifida, and cases of isolated sacral agenesis (our case and that of Lozzio et al.12) could be explained if the genes were not allelic, as proposed by Lynch et al.,9 but rather contiguous, with deletions in specific loci giving rise to

different phenotypes depending on both the position and extent of the deletion.

It appears that the 7q36 region contains a gene or genes crucial for the normal development of both ends of the neural tube. Deletions of this region may result in a phenotype owing to haploinsufficiency through either loss of function of the gene(s) caused by its disruption at the rearrangement breakpoint or monosomy for the gene(s) involved.

Addendum

Since submission of this paper for publication, mutations in the human Sonic Hedgehog gene, which maps to 7q36, have been identified in several autosomal dominant holoprosencephaly families.13, 14
