Abstract
This study reports the molecular characterisation of the bilirubin UDP-glucuronosyl-transferase gene (UGT1) in a group of patients of Sardinian descent with Crigler-Najjar syndrome type I and their relatives.

Sequence analysis of both UGT1A exon 1 and common exons 2-5 was performed in all patients, leading to the detection of AF170 and a novel mutation (470insT), both residing in UGT1A exon 1. All but two heterozygotes for the AF170 mutation showed normal serum bilirubin levels. These two subjects were also heterozygous for the sequence variation A(TA)7TAA in the promoter region of the UGT1A gene.

Keywords: CN1; mutation analysis; Gilbert syndrome.

Crigler-Najjar (CN) syndrome is an inborn error of metabolism, which is characterised by severe unconjugated hyperbilirubinaemia resulting from defective activity of the hepatic enzyme bilirubin UDP-glucuronosyl-transferase (UGT). CN syndrome has been classified into two types according to the degree of hyperbilirubinemia and response to phenobarbital administration. In type I, the level of unconjugated bilirubin in serum is usually above 340 μmol/l and phenobarbital treatment does not reduce it significantly. Type II patients have serum bilirubin levels in the 120-340 μmol/l range and respond to phenobarbital treatment by a decrease of at least 25% of bilirubin levels. CN-I is inherited as an autosomal recessive disorder, whereas for type II both autosomal recessive and dominant inheritance with variable penetrance have been reported.

The recent identification of a large gene locus termed UGT1, which encodes a family of UDP-glucuronosyl-transferase (UGT1A-UGT1M) including the two bilirubin transferase isoforms, has provided the tools for studying hereditary/unconjugated hyperbilirubinemia at the molecular level.

The complex UGT1A-UGT1M codes for at least two bilirubin transferase, three bilirubin-like, and eight phenol-transferase isozymes. In the 5' region of the locus, a minimum of 13 different exons 1 are located, each with an upstream specific promoter, while the 3' region contains four common exons. Each exon 1 encodes the amino-terminus of a specific transferase and the common exons (2-5) encode the common carboxyl-terminus of each isoform. The product of the UGT1A gene is the predominant bilirubin isoenzyme in liver, while the product of the UGT1D gene is the less abundant and phenobarbital responsive bilirubin transferase isozyme.

Mutation analysis in patients with Crigler-Najjar type I has detected deletions, nonsense and missense mutations most commonly in the common exons and occasionally in the unique specific exon of the UGT1A unit. This finding of mutations in the specific exon 1, together with the transfection experiments in COS cells, indicates that the UGT1A unit codes for the only relevant isoenzyme in bilirubin glucuronidation. In the few patients with CN-II analysed molecularly to date, missense mutations in the specific exon 1 of the UGT1A unit, or in common exons, have been detected, in some cases associated with missense mutations of unique exon 1 of the UGT1D gene.

More recently, patients with Gilbert syndrome, the mildest of the inherited hyperbilirubinemia, were found to be either heterozygous for missense mutations in the specific exon 1 of UGT1A or in the common exon 4 or 5, or homozygous for an extra TA dinucleotide in the TATA sequence of the promoter region of UGT1A (A(TA);TAA instead of the normal A(TA);TAA).

Here, we describe the results of the molecular characterisation of the UDP-glucuronosyltransferase gene in a group of patients of Sardinian descent with Crigler-Najjar syndrome type I and their relatives.

Patients
We have examined five patients with severe unconjugated hyperbilirubinemia belonging to four families of Sardinian descent. All patients, who were born to non-consanguineous parents, had persistent non-haemolytic hyperbilirubinemia (peak bilirubin levels >30 μmol/l). One patient (PE) required an exchange transfusion during the neonatal period because of a sudden increase of bilirubin levels (547 μmol/l). An exchange transfusion was carried out in infancy in patient PL, whose bilirubin levels increased up to 684 μmol/l with associated signs of neurological dysfunction (slurring of speech, drooling, reduced control of truncal tone, abnormality of fine hand movements, and moderate ataxia). This patient also had a mild form of dyskinetic central palsy with intelligence in the low-normal range. The bilirubin levels in all patients were unresponsive to phenobarbital administration. Figure 1  Family pedigrees of PEd. II.6 and II.7 have Gilbert syndrome. III.10 is the proband homozygous for the ΔF170 mutation. 6/6 genotype = A(TA)TTA(A(TA))TA, 6/7 genotype = A(TA)TTA(A(TA))TA. * = STB concentration (μmol/l). * above families = members not tested.

Reduction of the serum bilirubin levels was observed with phototherapy, which was used continuously in all the patients. Patient PL also required sporadic plasmapheresis to reduce the toxic high bilirubin levels. Liver biopsy was carried out in patient PL, in whom hepatic UDP glucuronosyl-transferase was absent. In two patients (CR and PL), aged 12 and 61/2 years respectively, orthotopic liver transplantation was carried out. After transplantation, the patients’ serum bilirubin levels rapidly returned to normal. These data are summarised in table 1. In six relatives of one of the patients investigated (PEd), who were found to be heterozygous for a mutation in the UDP glucuronosyl-transferase gene, we carried out serum total bilirubin determination (STB). The results were normal in all but two, who had been previously diagnosed as affected by Gilbert syndrome (fig 1).

Mutation analysis

Sequence analysis of both the specific exon 1 of UGT1A and the common exons 2-5 in all the five patients showed two mutations in exon 1, the previously described deletion of the phenylalanine codon (TTC) at position 170 (ΔF170) of UGT1A and a novel mutation, the insertion of a T at codon 158-159 (470insT), which results in a frameshift and in the production of a downstream stop codon (TGA) at position 182 (fig 2). Of these patients, three unrelated ones were homozygotes for ΔF170 and two sibs were compound heterozygotes for ΔF170 and 470insT. Of the 10 chromosomes carrying a defective UGT1A gene, eight thus contained the ΔF170 mutation.

The ΔF170 mutation may be easily detected by electrophoretic separation of a 401 bp DNA fragment containing the mutation on a 2 mol/l urea, 6% polyacrylamide gel. The 401 bp fragment was amplified with forward primer

AGCTCATGGCCTCCCT and reverse primer GATGGCCCTAGGGTAAT for 25 PCR cycles at 94°C for 30 seconds, 55°C for 30 seconds, 72°C for one minute in a Perkin-Elmer Cetus Thermal Cycler 9600 (fig 3). This procedure was used for screening the relatives of patient PEd. Six of them, hetero-
zygous for the ΔF170 mutation, were investigated for the A(TA)₇TAA at variation. Only the two subjects with increased STB concentration in this group showed heterozygosity for A(TA)₇TAA, the others being homozygous for A(TA)₇TAA.

Discussion

In this study, we have characterised the molecular defect in the bilirubin UDP-glucuronosyl transferase gene in five patients affected by Crigler-Najjar syndrome type I belonging to four families of Sardinian origin. We found three patients homozygous for a previously described mutation, the deletion of the phenylalanine codon at position 170 (ΔF170) of exon 1 of UGT1A, and two patients from the same family compound heterozygous for ΔF170 and a novel mutation consisting of the insertion of a T at codon 158-159 (470insT) of exon 1 of UGT1A.

The ΔF170 mutation has been previously described in a single patient of caucasian origin. This mutation abolish a conserved dihydroxaline at this position and results in the production of one third level of mRNA and presumably mutant protein as compared to the wild type gene. Furthermore, the mutant protein has no enzymatic activity at low pH (6.4), which is the optimum pH for bilirubin glucuronidation.

The 470insT mutation results in a frameshift and downstream stop codon, thus probably leading to absent protein product or to the production of a shortened functionless protein. Both mutations detected in this study reside in the specific exon 1 of UGT1A. This finding is consistent with the notion that UGT1A codes for the only relevant enzymatic isomor in bilirubin glucuronidation.

It is interesting to note that seven of eight mutant alleles from unrelated patients of Sardinian ancestry carry the ΔF170 mutation. This may indicate that Crigler-Najjar syndrome type I in Sardinia is prevalent because of a founder effect. A similar effect has been previously detected for Crigler-Najjar syndrome type I in France, Portugal, Turkey, and Tunisia.

In six heterozygotes, all belonging to the same family, STB levels and promoter sequence variation were studied. Four of these have normal STB levels and absence of the promoter variation A(TA)₇TAA. Normal STB concentration has to date been reported in subjects heterozygous for mutations that, most likely, cause absence of protein product or production of a shortened functionless protein. Tetramers are thus assembled only from the normal subunits, probably resulting in 50% normal activity, which may be sufficient for bilirubin metabolism in normal conditions. This could be a reason for the normal STB values shown by these subjects. Two of the ΔF170 heterozygotes examined showed high STB levels (>40 μmol/l) and the presence of the sequence variation A(TA)₇TAA in the heterozygous state. The sequence variation, although found in the heterozygous state, could explain the mild increase of STB concentration in these subjects. Recently it has been reported that a consistent decrease of the enzymatic activity of the UGT1A gene may also occur in those patients with Gilbert syndrome who are homozygous for the variant A(TA)₇TAA promoter. The transfection of a construct containing the A(TA)₇TAA promoter linked upstream to the firefly luciferase gene in a hepatic cell line led to a reduced luciferase expression, that is, 18 to 32% of that recorded in the presence of the normal TATA sequence motif (A(TA)₇TAA).

Further molecular analysis and mutation-phenotype correlation of patients with CN-I, CN-II, and Gilbert syndrome are needed to have a clear picture of the molecular pathogenesis of these inherited hyperbilirubinemia.
