Myotonia congenita in northern Finland: an epidemiological and genetic study

P Baumann, V V Myllylä, J Leisti

Abstract
An epidemiological and genetic investigation of myotonia congenita was carried out in northern Finland. Altogether 58 patients were identified (of whom 54 lived in the study area) in 23 families, with a prevalence of 7.3 per 100,000. The majority of the families originated from a sparsely populated area in western Lapland.

The mean age at onset of the disease was 11 years with a range of 2 to 45 years. The mean time that had passed before verification of the clinical disease was 18 (SD 14) years. The sex ratio M/F was 2.2/1.0.

Forty-seven cases were familial and 11 were sporadic. In six families/pedigrees the inheritance was compatible with autosomal recessive and in two families with autosomal dominant inheritance. In five additional families, in which autosomal recessive inheritance seemed most plausible, vertical transmission was also noticed. This could be explained either by consanguinity of the parents or by variant expression of the mutation(s) involved.

Our results suggest that myotonia congenita is unusually frequent in northern Finland, most probably as a consequence of an enrichment of the gene mutation(s) in the population.

Patients and methods
The study area consisted of the provinces of Oulu and Lapland and the northern part of the province of Vaasa, with a total population of 732,000. The basic family material consisted of the families seen at the Departments of Neurology and Clinical Genetics at the Oulu University Hospital. Additional patients were ascertained retrospectively from hospital records and registries of Oulu University Hospital and the central hospitals of Kajaani, Kokkola, Kemi, and Rovaniemi, from the years 1974 to 1995. Furthermore, a call for patients with myotonic symptoms was addressed to the neurologists, paediatric neurologists, and general practitioners in the area of the investigation. The obtainable first degree relatives (healthy sibs included) were studied for microsymptoms, both clinically and electrophysiologically, in order to exclude or verify signs of myotonia.

The clinical diagnostic and inclusion criteria for the disease were as follows: muscle stiffness, muscle function improving with continuing exercise (action myotonia), variable muscle hypertrophy, and myotonic bursts on intramuscular electromyography (EMG). The clinical criteria are in accordance with those set out by the European Neuromuscular Centre Workshop.

All the patients underwent a careful neurological and EMG examination. Genetic studies included family history and, in selected cases, tracing of common ancestors with the help of church records.

For the prevalence estimate, all patients living in the study area in 1995 were included. The evaluation of onset of the disease was based on the history given by the patients or their parents or both.

The study protocol was approved by the Ethics Committee of the Medical Faculty,
University of Oulu. Informed consent was obtained from each subject participating in the study.

Results
The main results are given in figs 1, 2, and 3. Fifty-four patients (39 males and 15 females) with MC were detected, giving a prevalence of 7.3 per 100 000 for the area investigated. The mean age of the patients was 41 years (range 6 to 75). From the years 1950 to 1979 it could be roughly estimated that 1.2 patients were born annually in the area investigated (fig 1). The domiciles of the patients as shown in fig 2 show a clustering of the disease for the cases in western Lapland.

The mean age at onset of symptoms was reported as 11 years and the majority (37 patients, 65%) fell in the age group between 6 and 10 years. Two of the patients experienced motor disturbance first after 16 years of age and one patient before 6 years of age. Two patients were not aware of myotonia before participating in the study. The mean time that elapsed before the diagnosis of the disease was 18 (SD 14, range 1 to 43) years.

The patients belonged to 23 families. Forty-seven cases were familial and 11 were sporadic (fig 3). Twelve patients belonged to a large family (A), which could be traced back to the late 18th century, originating from western Lapland. In this family several instances of either parental consanguinity or close relationship with parents of other patients were found. In three additional families (B, C, and F, 16 patients) with probable autosomal recessive inheritance of the disease, vertical transmission was also seen. In two families (D and E, six patients) transmission was compatible with an autosomal dominant mode of inheritance. In six families (G to L, 13 patients) autosomal recessive inheritance was most plausible. The rest of the cases (M to W, 11 patients) were sporadic.

Discussion
The prevalence of MC in northern Finland, 7.3 per 100 000, is exceptionally high and partly reflects the systematic search for patients both from medical records and from close family members. On the other hand, the high prevalence rate could also be explained by a founder effect or careful neurological and EMG examination; thus even relatively mildly affected people could be included. As shown in fig 1, it can be roughly estimated that 1.2 cases are born annually. It is also probable that the disease is more common in the area studied for genetic reasons. Several rare recessive diseases have accumulated in the Finnish population owing to the enrichment of the respective gene mutations. It is possible that the gene(s) causing MC have also been enriched, especially in western Lapland, by the same mechanism of isolation by distance as in the other diseases of the Finnish disease heritage. There is only one larger study on the frequency of MC. In this study from West Germany and West Berlin, a frequency of 0.2 per 100 000 (116 cases) for dominantly inherited and 0.3 per 100 000 (150 cases) for recessively inherited clinically verified myotonia were reported, respectively.

Incomplete ascertainment of the patients was, however, assumed. In a smaller study by Pinessi et al (10 cases), a prevalence rate of 0.9
Myotonia congenita in northern Finland per 100,000 from the city of Turin, Italy, was reported. In our study the sex ratio was 2.2:1.0 in favour of males. In the German study of Becker, it was assumed that, in the dominant form of the disease, the sex ratio is approximately even and in the recessive form a slight preponderance of male patients was found. Our results indicate that the disease is clearly more common in men than in women. The reason for this is unknown.

The mean age at onset of myotonia as reported by our patients or their parents was 11 years; 65% of the patients experienced myotonia between their 6th and 10th year of life and an additional 27% before the age of 16. The true onset of the disease process was probably earlier, as shown by the two asymptomatic cases who were detected by the EMG registration. It is also possible that the early symptoms of the disease, that is, mild motor performance disturbance, have not been recog-

nised as symptoms of the disease. This could also explain the relatively long time that was needed for diagnosis (18 (SD 14) years). Becker suggested that dominant myotonia most often starts in the first three years of life, whereas the usual age at onset in recessive myotonia is between the fourth and twelfth years. The disease is thus often experienced as relatively mild and medical aid is sought late. This assumption is supported by the findings of Baumann et al., who suggested that the overall output of the motor performance of myotonic patients is not greatly impaired. On the other hand, MC patients keep their myotonia a secret, even from general physicians. The rapid development of neurological diagnostics during the last decades has shortened the delay in reaching a diagnosis, as seen also in the present material.

Even when vertical transmission of the disease was seen in several families, autosomal recessive inheritance seems the most plausible mechanism to explain most of the familial occurrence of the disease. In the largest pedigree (A), several instances of parental consanguinity could be shown to explain the occurrence of the disease, both in parents and their children. It is also possible that a mutation(s) prevails in the population which allows the disease to become manifest in heterozygous and homozygous forms. Molecular studies that are in progress should explain the genetic features of this exceptional prevalence of the disease in northern Finland.

We conclude that MC is unusually frequent in northern Finland, most probably as a consequence of enrichment of the gene(s) in the population.
