Surveillance or surgery? A description of the factors that influence high risk premenopausal women’s decisions about prophylactic oophorectomy

Nina Hallowell, Ian Jacobs, Martin Richards, James Mackay, Martin Gore

EDITOR—Approximately 5% of cases of epithelial ovarian cancer result from an inherited susceptibility.1 Some of the genetic mutations responsible have recently been identified.2-3 It is estimated that BRCA1 carriers have a 28% lifetime risk of developing ovarian cancer,4 while BRCA2 carriers have a risk of 0.4% of developing ovarian cancer at the age of 50, which rises to 27% by the age of 70.5 The recommended management of high risk women is either annual ovarian screening (transvaginal ultrasound) with serum CA125 measurement or bilateral prophylactic oophorectomy from the age of 35 onwards, or once childbearing is completed.6-11 As there is no evidence that ovarian screening is effective in reducing mortality, it is currently assumed that prophylactic surgery is the best form of risk management;12-14 although data suggest that intra-abdominal carcinomas may still arise following this procedure.15-17

There is little published research on the uptake of preventative surgery in at risk women18 or mutation carriers.19-20 However, it is generally assumed that there will be an increase in demand for prophylactic surgery, as direct mutation testing becomes more widely available. Epidemiological studies suggest that prophylactic oophorectomy may play a role in the prevention of breast cancer in high risk populations.21-22 Therefore, there may be a case for informing women at risk of breast cancer about this option. If health professionals are to facilitate informed decision making about ovarian cancer risk management, then they need to be aware of the factors that influence women’s decisions about prophylactic surgery.

There are few published data that describe the factors that influence women’s decisions to undergo prophylactic surgery because of their inherited risk of developing cancer. Studies of high risk women who have undergone prophylactic mastectomy to manage their risk of breast cancer suggest that surgical decisions are influenced by subjective risk perception and cancer worry, attitudes about the menopause, and social obligations.23-26 While this research is informative, it can also be seen as problematical because (1) prophylactic surgery was a hypothetical option for some of the women in these studies, in the sense that there was no indication that they were seriously considering this form of risk management, and (2) the menopausal status of participants was not reported. With regard to the latter point, it can be speculated that, because oophorectomy results in menopause, surgical decisions may be influenced by current menopausal status.

The present study of surgical decision making has tried to overcome the shortcomings of previous research on prophylactic oophorectomy, by interviewing high risk women who have previously undergone prophylactic surgery before the menopause, together with premenopausal women who have rejected this option for the present.

Methods

RECRUITMENT

The participants were recruited from the United Kingdom Cancer Coordinating Committee’s Familial Ovarian Cancer Register, the Risk Advisory Clinic at St Bartholomew’s Hospital, London, and the Cancer Family History Clinic at the Royal Marsden Hospital, following LREC approval for the study. Information about menopausal status before surgery or at the time of interview was available for women recruited from the UKCCCR register; for the remainder of the sample, whose menopausal status was unknown, 45 years of age was used as an arbitrary cut off point for recruitment. With the exception of one affected woman, only women who had at least two first or second degree relatives affected with ovarian (or breast) cancer were approached to participate. All women in the surgery group were recruited from the UKCCCR register, and therefore had two relatives with ovarian cancer. With the exception of two women who had no affected first degree relatives, one of whom had a paternal family history, all had a 50% chance of carrying a mutation. Sixteen women in the screening group were recruited from the register and the remaining women were recruited from the clinics mentioned above. In the case of women recruited from the clinics, only those
with a family history consistent with HBOC were recruited, which meant that they had at least one relative with ovarian cancer and other relatives with breast cancer. Eight women in the screening group had no affected first degree relatives, although one of these had been treated for breast cancer. Thus, 19 women in the screening group had a 50% chance of carrying a mutation and seven were at 25% risk of carrying a mutation. Of these seven women, three had a paternal family history and four a maternal history. In three of the latter cases their mother had undergone therapeutic or prophylactic oophorectomy because of the family history of ovarian cancer.

DATA COLLECTION AND ANALYSIS

In depth interviews (one to three hours) were carried out in a location of the participant’s choice (see box 1). All interviews were tape recorded with consent and transcribed. Consent to analyse the tapes was also obtained at the end of the interview. A thematic analysis of the interview transcripts was undertaken using Atlas-ti to manage the data. The data were initially indexed on a case by case basis, which allowed patterns and relationships between the codes to emerge within the data set. Between interview comparisons were also made and this enabled deviant cases to be taken into consideration. The resulting themes provided an all inclusive description of participants’ accounts of surgical decision making. The frequencies with which some responses occurred are noted in the presentation of the results. While this should not be interpreted as indicating the relative importance of the different responses, it does provide an indication of their representativeness within this data set.

Results

The surgery group, who were invited to participate, included 33 women from the Familial Ovarian Cancer Register who had undergone surgery and met the study criteria. Ten failed to reply and 23 (70%) women from 17 families were finally recruited. The screening group, who were contacted by letter, included 34 women who were currently undergoing screening and/or had attended genetic counselling. Three refused to take part and five did not respond; 26 (76%) women from 24 families were recruited. The demographic and cancer family history variables of the participants are summarised in table 1.

*Women with only one affected relative were themselves affected with breast cancer.
†One woman had ceased screening and another was about to start screening.
‡In five cases, oophorectomy was performed following abnormal screening results/during an exploratory operation.
§Four women had previously undergone therapeutic hysterectomy.
The analysis of the interviews with women in both the screening and surgery groups suggested that there are five main factors that influence surgical decisions. These can be summarised as: (1) risk perception and the risk of cancer, (2) witnessing a relative’s experience of ovarian cancer, (3) family and social obligations, (4) fertility and menopause, and (5) fear of surgical procedures in general. Where appropriate, the following discussion will compare the responses of those who had undergone or rejected surgery (for the present) to highlight points of continuity and difference between the two groups.

(1) RISK PERCEPTION AND THE RISK OF CANCER

Others have observed that risk perception and cancer worry may influence the decision to undergo surgery. Similar observations were made in the present study, for with one exception, all of the women in the surgery group reported experiencing a great deal of anxiety about their ovarian cancer risk before the removal of their ovaries. Eight women said they had previously viewed their risk in absolute terms, and had undergone oophorectomy because they believed that they would definitely develop ovarian cancer in the future. (To maintain the participants’ confidentiality all the names used in this paper are self-chosen pseudonyms.)

Julie: “My own personal reason was, I had the operation because I didn’t want to die. That’s how I looked at it. And I was really, really concerned that because of the history that we’ve got, that I would get ovarian cancer, even though I was being screened regularly. . . . And I would honestly say that I was so concerned that I would get the cancer. . . . I thought, no, I’ve got to have it done. I don’t want to die. That’s how I ended up. I don’t want to die. I thought, I’m not going to die, I’m going to have this operation no matter what.”

Ten women claimed to have viewed their risk probabilistically, and said they used to think of themselves as having a higher risk of developing cancer than other women because of their family history. Seventeen women reported that their fear of developing cancer had been an influential factor in the decision to undergo surgery, and all the women in the surgery group reported feeling an overwhelming sense of relief following oophorectomy. They said they no longer perceived themselves to be at risk and no longer felt afraid or worried about developing ovarian cancer.

Sue: “Certainly the worry taken away is worth everything else because . . . it was a big worry especially since my sister died. I mean when it was just my mum it was one of them things, then it was my auntsies . . . and then when it starts on your sister you think... that worry taken away just made such a difference.”

Five women in the screening group perceived their risk in absolute terms and were convinced they would develop ovarian cancer in the future (three of these planned to undergo prophylactic surgery), while 16 women said they perceived themselves as at increased risk compared with the general population. Fourteen women said they needed more information about their risk of developing ovarian cancer before they would seriously consider prophylactic surgery. More specifically, they suggested that confirmation of their mutation status would help them to make a decision about surgery, as Nicola said: “If I knew that I had the defective gene I would have surgery without a doubt.” This contrasts with women in the surgery group, who, with one exception, had undergone surgery without verification of their mutation status. However, it must be noted that in many cases this option was not available at that time.

Other women in the screening group indicated that, even if they were confirmed as mutation carriers, they would not proceed with surgery on the basis of increased cancer risk alone.

Carol: “It’s like sort of - I don’t know, cutting your arm off for a scratch on your finger . . . even if they identify me as having the gene, they say you may or may not get cancer from it. You may still not get cancer from it all your life. I just think it just seems - to cut out healthy organs as a preventative measure seems drastic, unless you’ve got one hell of a case for doing that.”

Susan: “On - on the whole - you know? I mean you can have the test, you can have the gene, but you still might not get the cancer. You might not have the gene, and you could still get cancer. Um... you know? So the - I mean I don’t know. Obviously they’re not going to know how many people who’ve got the gene go on to develop the cancer, are they?”

Some women in the screening group also expressed scepticism about the efficacy of prophylactic surgery in containing/lessening the risk of ovarian cancer. They reported receiving confusing messages either from their doctors or the media about whether surgery would prevent cancer occurring.

Katrina: “Well, nobody seems to know really if it [surgery] is beneficial or not. I get sort of not conclusive answers, really. It’s almost as if, um, well, give it a try. We think it may be beneficial. And some consultants do it, some don’t.

And it’s this conflict of opinion that - it confuses you really . . . I think if I conclusively knew that there was a big reduction in the risk, I would probably opt for it. But as it’s still up in the air at the moment, I’m just going to stick with screening for the moment.”

Moreover, 10 women said they did not perceive surgery as a viable option because of the residual risk of developing peritoneal cancers.

Carol: “If they could say, you’ve inherited the gene - but they can’t tell me that either. It’s a gamble, I know. And my sister was told at X by the consultant there, even having your ovaries removed wouldn’t really make the risk - because there’s still ovarian cells in the rest of your body from um when you’re in the embryo stage. Apparently there’s ovarian cells still in your body that could turn cancerous. Just a very, very remote chance, but there is a chance.”
Some of these women were uncertain about where these cancers might develop and worried that they might be potentially “less detectable” with screening.

Sarah: “Oh, one of the things I would worry about is the risk of this little bit of ovary being left behind, and if that did happen - she said, oh, it was very, very minimal, but if that did happen, and some cancer started growing there, where would it start growing next? What sort of direction? Like I say, they may not know, but where would it go? So what - if it started growing on another organ, what would the consequences of that be?”

As far as some women in the screening group were concerned, it was important to keep their ovaries because they constituted a target organ for cancer to develop in/on. Indeed, because these women believed in the efficacy of ovarian screening, they felt their risk of cancer would be better managed, at least for the present, by keeping their ovaries and having them monitored.

In contrast, only one woman in the surgery group reported that she was aware of the risk of peritoneal carcinomas following surgery, while another recalled being told that her risk of breast cancer was increased because she had undergone ovarian surgery. With these exceptions, there was no evidence that women in the surgery group had taken the residual risk of developing peritoneal cancer into account when making their decisions. This line of questioning was not pursued during the interview for ethical reasons.

Finally, two women in the screening group said that they would like more information about the symptoms of ovarian cancer and the efficacy of screening, particularly the prognosis of cancers detected during screening.

Vicky: “I mean I think, you know, the implications of if you do get it, how quickly it - and how deadly it is, actually. It’s pretty horrible, isn’t it?”

(2) WITNESSING A RELATIVE’S EXPERIENCE OF OVARIAN CANCER

Cancer risk management decisions were frequently described as influenced by people’s former experiences of ovarian cancer, particularly nursing a dying relative. Many women talked at great length and very emotionally about their mother’s or sister’s illness. Indeed, many of those in the surgery group said that the death of their mother or sister or a relative in their generation (for example, a cousin) had been one of the most influential factors in their decision to have their ovaries removed.

Linda: “I suppose I might have been luckier than some, with actually having seen a lot of what goes on, with my mother, as well. I’m - you know? - I’m aware of what happened. Some people don’t ever see that. They don’t ever see that side, you see. So um when I saw that, then that’s another fact that made me you know, that helped towards me making my mind up.”

Pam: “No, I think knowing that - how my mum looked, and what she suffered, or what she must have suffered, I thought, there’s no way I’m going to do that. I mean the poor lady, I mean they drained 19 litres of fluid off of her, and it still came back. She was like a beached whale. And I thought, how can anybody suffer like that? And how long had this been going on? And they say it’s one of the fast-growing ones, because it’s hormonal. And I thought, well, there’s no way. Because I wouldn’t want my children to see me go through that agony.”

Similarly, some women in the screening group acknowledged that their past experiences with ovarian cancer were an important influence on both their risk perception and attitudes about future cancer risk management.

Mary: “I think the biggest influence for me is seeing personally at first hand people dying of it. There’s no doubt that that brings it home to you, and I’d prefer not to go down that route . . . I mean I don’t want to end up in the pitiful state that my mother was in. I’ve seen that, and I remember her suffering. I can see her crawling across the floor on her hands and knees, because she was in so much pain. And after seeing something like that, if hysterectomy is the answer, then I’ll go for it . . . I think it might be a harder decision for somebody to make who hasn’t seen anybody with the illness, who’s never come into contact with cancer of any form, because it’s the nasty word, people don’t - well, they talk about it more than they used to, but a lot of people don’t come into contact with it. And having seen people with it, and just what it does to them, and the family round them, I don’t want to go - I’ve no intention of going through that, if I can help it. So if they said, you’ve got to have your right arm off at the same time, I’d do it. I’d do it.”

While others were aware that their lack of first-hand experiences of others’ suffering had influenced their risk perception and attitudes about prophylactic surgery, they felt at less risk and were less inclined to opt for this risk management option.

Susan: “I think they’ve [cousins] got a very negative - I mean obviously it’s hard for them, because they - I don’t know, I think their mother died possibly, or, um - whereas, you know, my mum’s still alive. I suppose if she had died, I would perhaps feel differently. But I do think they put across a negative attitude, that if you’ve got this gene, you’re going to get it and you’re going to die unless you - you know, unless you take this drastic - have this drastic surgery . . . Unless I had a cancer, I don’t think I would take it as a preventative medicine, because you have to keep cutting bits out, you know. That’s how I feel. But um, you know, obviously I haven’t had - I haven’t seen somebody die from it.”

The importance of witnessing a relative’s experience of ovarian cancer may account for the fact that 87% of the women who had undergone surgery had first degree relatives who had died from ovarian cancer, compared with only 41% of women in the screening group. Indeed, the women in the surgery group, and those currently considering surgery in the screening group, also reported experiencing high levels of anxiety about developing
ovarian cancer before surgery, which many acknowledged had been explicitly influenced by their experiences of cancer in the family. This observation suggests that those who have not witnessed ovarian cancer in a close relative, for example, women with a paternal family history, may be less inclined to opt for surgical risk management. There was some evidence of this in the present study, as the screening group contained a larger proportion (19%) of women with a paternal history than the surgery group (4%).

(5) FAMILY OBLIGATIONS
As has been noted elsewhere, high risk women frequently describe themselves as having an obligation to their family to manage their cancer risks. Similarly, in this study, none of the women in the surgery group described their decision to undergo surgery as a decision they made just for themselves; indeed, nearly all the women said that they had a responsibility to their family to prevent ovarian cancer occurring. They described themselves as having had a responsibility to undergo surgery to ensure they remained healthy so that they could raise their family.

Linda: “My son, my husband, I think deep down, my son more than anything... I wanted to be around for him you know I didn’t want like my mum lost her mum at age 10 and my sister was 19 no 20 something... but I wanted my son to have me here as long as possible, and I fI ‘d been with my mum...I fI ‘d been more with my sister and with my mother.”

Victoria: “I mean I knew I had to. Once the [mutation] test was positive, I knew I had to have it [surgery], because of the chances. But I never felt that I would actually get it. I couldn’t take that chance, and my husband didn’t want me to. And if it did happen, I didn’t want my children to suffer how I suffered with my mum and even more so with my sister. . . If I’d been on, a single person on my own, I might not have. I don’t know. I just didn’t want my children to go through what I’d been through with my sister and with my mother.”

Familial obligations also influenced decisions about the timing of surgery. All the women acknowledged that social support during convalescence was important. Some in the surgery group had postponed surgery until the summer holidays so their children could help out, others timed their admission to hospital so that their in laws or partners could look after the children. For one woman with very young children, the option of surgery only became a possibility once she found out that she was entitled to a home help supplied by social services.

However, familial obligations not only influenced decisions to accept surgery, but also to reject it. Seven women in the screening group said their decision to continue screening, rather than undergo surgery, was affected by the long period of convalescence needed following surgery, and the effect that it would have on their ability to provide practical and economic support for their family.

Katrina: “I’d want to know the recovery time, and the time out I’d have to take from work, which is very important for me because I’m a single parent now, so I haven’t got a husband ready to take over. Which also is a personal reason for me not opting for it. . . I mean it’s social reasons are one of the reasons why not, as far as I’m concerned. If I was married and had a husband at home earning a wage, I could quite possibly consider it. But as I’m the only - you know? - wage earner and stuff like that, I have to consider that as well. I suppose we could live on [unclear] for six months [unclear, laughter].”

Others rejected the idea of prophylactic surgery on the grounds that their admission to hospital would potentially cause emotional upset within the family. In particular, the women who had previously undergone therapeutic surgery for breast cancer talked about the effect of their cancer treatment upon family dynamics, and were very keen to avoid causing their family any further anxiety by seeing them hospitalised again.

I: “Are there any other reasons that put you off having surgery?”

Barbara: “No, nothing else. It’s just that I just don’t want to go through all that again. Really don’t want to go through it again. It was just traumatic last time. Not the actual surgery as such, but the trauma thing of leaving here to go and have it done. You can imagine, leaving your children and thinking, oh, I’ve got to go back in there again. Oh, I can’t go through that. And I keep thinking, you know, I keep thinking I’d be really unlucky to get breast cancer and ovarian cancer. You know? But I’m prepared to take the chance.”

(2) OVARIAN FUNCTION: FERTILITY AND MENOPAUSE
All the women knew that ovaries have a reproductive function and infertility following oophorectomy was seen as a major influence on risk management decisions. All those in the surgery group said they had taken this into account when making the decision. In most cases when their doctor first mentioned surgery, they had already completed their families. However, two women said they had postponed the operation for a few years because they were not sure about having more children.

Nine women in the screening group also described their decision to continue screening as specifically influenced by the need to maintain their fertility for the present, although one woman said that if surgery were necessary she would consider adoption.

I: “What do you think would happen to women who had their ovaries out at 26?”

Abby: “I just think they’d be extremely depressed. Definitely. The thought of you not...”
Letters

being able to choose to have any more children yourself - I don't - I didn't then, I didn't want that decision taken away from me. That was my decision, nobody else's, and I didn't want that taken away from me."

Sandra: “But all the time I'm 37 and under forty especially and I've only got the one child, that is the reason, because it would take all my options away, and er you just don't know. That is the main reason. It would completely take my options away.”

Six women in the screening group and five in the surgery group were not aware of the hormonal functions of the ovaries at the time of the interview or before their operation, respectively. These women said they did not know, or had not known, that the removal of their ovaries would result in immediate menopause or that they would need hormone replacement therapy (HRT) after surgery. The remaining women in the surgery group said they had been aware they would be menopausal following the operation, and some said they had been worried about the effects of menopause before surgery.

Julie: “And I had visions of me having hairy legs and beard and broken bones and - you know, like an old person.”

On the other-hand, 14 of these women said they had been unaware of the specific menopausal symptoms that they could, or did, experience postoperatively.

Fifteen women in the screening group said their attitudes to prophylactic surgery were influenced by their concerns about the physical and psychological sequelae of surgical menopause.

Emma: “I suppose I think in a way, er, the effects, hormonal effects, on your body.”

I: “I mean what sort of - apart from the bones [laughter] what other effects do you think there would be? What side effects?”

Emma: “I suppose being less feminine. I don't know if that's a mental thing as well.”

I: “Yes. And what do you sort of mean? In what sort of a way?”

Emma: “Um... I don't know. I suppose you think of like growing facial hair, and - I don't know, perhaps does it alter your figure or - you know? Do you start losing your hair? You know? It's that kind of a thing, I suppose.”

Four women in the screening group, who were aware of other potential health risks associated with a surgical menopause (for example, the increased risks of osteoporosis and cardiovascular disease) said they would like more information about the most appropriate age to undergo ovarian surgery.

Jenny: “But it's being in the limbo and not knowing when's the appropriate age to have it done.”

Although 17 women in the surgery group recalled being told that they would have to take HRT following surgery, many said this was the only information they received. Most reported that they had felt less anxious about the menopausal side effects of oophorectomy when they were told, before their operation, that they could take HRT, although one woman described how she had worried that the HRT might make her more emotionally labile.

Eve: “I know one of the things I did say to him [gynaecologist] about HRT was I didn't want it to make me a Jeckyll and Hyde character, because even with my periods before hand I was very very even, I didn't peak and trough through the month um . . and I didn't want that.”

The data suggest that women want and need much more information about HRT both before and after surgery. Seven women in the screening group expressed concerns about the history of breast cancer in their family and had interpreted press coverage of breast cancer and HRT as meaning they would be unable to take HRT following an operation. Women in the surgery group voiced similar concerns. They said that they worried about HRT increasing their risk of breast cancer and had received conflicting information from their doctors and/or the media. The most frequent types of questions about HRT asked by women in both groups were summarised by Jenny as follows.

“I'm going to need HRT. Can I get away without HRT? How am I going to increase my personal risk of CA breast if I go on HRT, given the family history? There's a new hormone-free HRT. Is that going to be banned before I can get my hands on it? Er, and what's the minimum-maximum period that I would stay on the HRT?”

(5) FEAR OF SURGICAL PROCEDURES

Seven women in the surgery group said that the decision to undergo surgery had been influenced by their fear of surgical procedures in general. In every case their anxiety about surgical procedures had meant that they had postponed making the decision for a few months.

Sue: “It never - it - apart from the surgery itself, which I was terrified of, actually having your ovaries taken away never, never bothered me . . . I'm so frightened of hospitals...I wanted one [oophorectomy], out of fear, but I didn’t want one out of fear of hospitals! [laughs]”

Fear of surgery similarly influenced the risk management choices of some of the women in the screening group. Eight women said their decision to continue ovarian screening was influenced by their fear of surgical procedures in general, for example, anaesthesia, pain, and postoperative complications.

Jane: “Surgery is a bit sort of frightening.”

I: “What sort of things frighten you about surgery?”

Jane: “Well it is just the thought of them cutting you up, and if anything went wrong, and you didn't wake up again . . .”

Jen: “And I'm also concerned with keyhole surgery...I've had laparoscopies, and I know it moves things around, because they blow your stomach up and things don't go back in the right place.”

The women who had previously undergone surgery for breast cancer also talked about their fear of surgical procedures. They were less likely to want to undergo further surgery for
Letters

689

prophylactic reasons, even if DNA testing showed they carried a mutation.

Barbara: "He [consultant gynaecologist] said, 'I strongly suggest you have them out'. And I thought about it and I thought, I just don’t want another operation. So I opted for the screening as opposed to the operation. And he did explain that the screening isn’t one hundred per cent. But that’s a chance I’ll take. . . . quite honestly I don’t want another operation. I am so scared of going under, and thinking, will I wake up again? You know? I just - being in hospital again, with all that business of the having the things aspirated, . . . Oh, no thanks. No, I’ll take the chance."

Discussion

The present study used qualitative methods to determine the factors that influence high risk premenopausal women’s decisions about prophylactic ovarian surgery. As others have noted, surgical decision making involves the weighing up of both positive and negative expectancies concerning the outcome of surgery. In the present study, this involved women balancing the gains of risk reduction, the relief of anxiety, and fulfilling one’s familial obligations to remain healthy against the potential costs of surgery, such as infertility and the onset of menopause, the continuing risk of developing what is perceived as a “less detectable” peritoneal carcinoma, and one’s inability to care for the family during convalescence. While it is difficult to draw firm conclusions from this study, because of the small number of women involved, the data raise some interesting questions for future research.

The interviews showed that decision making about cancer risk management is a complex process, involving the consideration of both individual and social factors, individual perceptions of cancer risk and the recognition of the effects of undergoing surgery upon the family. Furthermore, surgical decision making emerged as a dynamic process, as shown by the fact that none of the women in the screening group had absolutely ruled out the possibility of prophylactic surgery at some future date. All the women who were currently undergoing ovarian screening acknowledged that they could change their minds about surgery, if their circumstances changed. This observation suggests that to divide these women into two distinct groups is to make a somewhat artificial distinction. However, as has been shown above, subtle differences were also apparent between the responses of the two groups.

As a recent study of decision making about prophylactic mastectomy has shown, risk perception and attitudes to breast cancer risk management appear to be affected by previous experiences of cancer in the family; similarly, some in the screening group hypothesised that they were less anxious because they had not had this experience. This observation may explain the recent finding that the consideration of prophylactic oophorectomy is positively associated with subjective risk perception and cancer worry rather than objective risk estimates. Indeed, the fact that a larger proportion of women in the surgery group had witnessed the death of a close relative from ovarian cancer may explain the fact that more women in the surgery group expressed the view that their risk of cancer was absolute than those in the screening group.

It was suggested that women who have a paternal family history of these cancers, and are therefore less likely to have witnessed ovarian cancer in a close relative, may be less inclined to opt for surgical risk management. However, research suggests that women with a paternal family history may opt for screening rather than surgery for other reasons. A recent study of at risk women and breast cancer patients indicates that they regard men as less likely to pass on the genetic mutation for breast cancer susceptibility than women. Thus, it is possible that women with a paternal history consider themselves to be at less risk of carrying a mutation and developing ovarian cancer than those with a maternal history, which indeed they are if they do not have an affected first degree relative. While there were not enough women in this sample with a paternal family history to substantiate these claims, what must be noted is that of the four women in the screening group with a paternal history, who had a 25% risk of inheriting a mutation, only one had attended genetic counselling and received this information. These observations suggest that there is a need for research that specifically focuses upon the attitudes and risk management practices of women who have a paternal family history of breast/ovarian cancer.

One of the main differences between the groups’ responses was the importance they placed upon establishing their mutation status before prophylactic surgery. It was observed that many of those currently undergoing screening said they would consider surgery if they were confirmed as a mutation carrier, in contrast to the majority of women in the surgery group who had undergone surgery without previous confirmation of their mutation status. This difference may be explained by the fact that most women in the surgery group had not been offered mutation testing before surgery; indeed, in some cases this was not an available option as the gene had not been identified at the time they were making the decision to undergo surgery. Given these observations, it can be argued that the responses of women in the screening group may provide a more accurate picture of the influence of mutation testing on surgical decisions. Indeed, the responses of the screening group concur with the findings of recent research which suggest that many women undergo BRCA1/2 testing to facilitate decisions about prophylactic surgery. Thus, it can be
hypothesised that as the availability of mutation testing increases, we may see more women postponing prophylactic surgery until they have received information about their mutation status. Clearly, there is scope for a prospective study that looks at the impact of mutation testing on risk management decision making.

Similarly, between group differences were observed with regard to women’s attitudes about the risks of peritoneal carcinomas. A large proportion of the screening group said that these risks had influenced their decision to reject surgery, whereas only one woman in the surgery group specifically mentioned these risks. As was noted above, it was thought unethical to pursue this topic with women who had already undergone surgery, on the grounds that if they were unaware of this risk, then providing them with this information could cause them anxiety. Therefore, as there is no evidence that the women in the surgery group had been told of this risk before surgery, it is impossible to say whether the risk of peritoneal cancer had any effect upon their decisions. However, the responses of the screening group suggest that providing women with this information does influence their risk management decisions. What was apparent from these women’s responses was that the smaller risk of a less detectable cancer developing following surgery was seen as a negative outcome of oophorectomy and this, when combined with other perceived costs of surgery, was used as a justification for rejecting the surgical option for the present.

Finally, this study can be seen as having implications for clinical practice. It suggests that if medical professionals are to facilitate women’s decisions about their cancer risk management, then they need to ensure that they receive clear information about the risk reducing benefits of prophylactic oophorectomy and the potential physical and emotional consequences of undergoing gynaecological surgery. Furthermore, medical professionals need to take into account the weight given to familial responsibilities in the decision making process. In addition to providing emotional care, women also provide practical care for their families and, particularly in families where they are the main or only wage earner, surgery may not be perceived as a practical risk management option. Medical professionals need to be aware of these practical and/or economic constraints on women’s cancer risk management choices and, if appropriate, provide information about agencies that can provide support.

In conclusion, it must be noted that the information needs of high risk women who consider prophylactic mastectomy are well provided for; in many centres within the UK they have access to breast care nurses and/or high risk women who have undergone prophylactic surgery. At present, similar support does not appear to be available for those undergoing prophylactic gynaecological surgery. This study suggests that an information and support network should be put in place for premenopausal women who are considering prophylactic oophorectomy. This could either involve the establishment of self-help groups in regional centres, the provision of gynaecological information and support pre- and post-surgery, or, at the very least, providing women with written information about prophylactic ovarian surgery and its potential after effects.

We would like to thank all the women who took part in this research, the Steering Committee of the UKCCCR Familial Ovarian Cancer Register, Carole Pye, and Amy Storfer-Isser, the staff at St Bartholomew’s and the Royal Marsden Hospitals particularly, Laura Hitchcock, Karen Cook, Karen Sibley, Audrey Aridgers-Jones, Ros Eeles, and Chris Horszopcz. Thanks are also due to Julia Lawton for her very helpful comments on an earlier draft of this paper. This research was supported by a grant from WellBeing (grant No HI97) to the authors.

Clinical genetics is an important aspect of family history assessment, and many oncology nurses are in an ideal situation to incorporate family history assessment into their practice. Oncology nurses are in an ideal situation to distinguish families at high risk from those who are concerned about their personal inherited risk but are in a low or moderate risk category. Ongoing involvement with patients and their families during the course of the treatment, post-diagnosis support, and palliative care lead to a trusting relationship between the patient and nurse and consequently the opportunity to discuss referral of family members. Some oncology nurses see genetics as an important facet of nursing practice and a role for oncology nurses in family history collection and assessment has been proposed.

Cancer genetics requires a shift in focus from the traditional nursing role. Oncology nurses have a patient-centred approach and well developed skills with respect to care of the patient; genetics requires the consideration of the family. Not only is information about the extended family required for assessment, but information given to patients may be directly relevant to, or impact on, other family members.

Oncology nurse training in cancer genetics

Clara Gaff, Kristiina Aittomäki, Robert Williamson

EDITOR—The rapid increase in understanding of cancer genetics in recent years means that few oncology nurses have sufficient knowledge to address the issues of patients concerned about inherited predisposition to cancer. While some nursing curricula have recently incorporated cancer genetics, this does not assist the large body of oncology nurses already in practice. The need for an educational programme in cancer genetics was highlighted locally by a focus group of senior level nurses and social workers practising in oncology (unpublished data). All felt inadequately equipped to deal with enquiries regarding family history and cancer risk from patients and staff. Nobody in the focus group was aware of the Australian guidelines for referral to familial cancer clinics within their employing organisations and family history was not routinely collected.

The Australian guidelines categorise families according to their level of cancer risk (“high”, “moderate”, or “low”) based on family history and/or the presence of a germline mutation known to predispose to cancer. In Australia, multidisciplinary Familial Cancer Centres provide genetic counselling, genetic testing, and risk management advice to those families judged to be at “high risk”.

Those categorised at low or moderate inherited risk of cancer may also benefit from informed counselling but may not meet the criteria for referral to the Familial Cancer Centres. As cancers are common, a significant number of people in the community with a family history of cancer will be in these categories. Many will not have a single gene mutation, but are at somewhat increased risk of developing cancer and require surveillance advice. The person’s perception of this risk may not reflect reality. People at moderate risk for breast cancer often overestimate their level of risk. After receiving counselling and a personal risk estimate, most report feeling less worried and their perception of risk is more accurate. These issues may be addressed by services focusing predominantly on surveillance and management issues rather than inheritance.

The Australian model requires relevant health professionals to incorporate family health assessment into their practice. Oncology nurses are in an ideal situation to distinguish families at high risk from those who are concerned about their personal inherited risk but are in a low or moderate risk category. Ongoing involvement with patients and their families during the course of the treatment, post-diagnosis support, and palliative care lead to a trusting relationship between the patient and nurse and consequently the opportunity to discuss referral of family members. Some oncology nurses see genetics as an important facet of nursing practice and a role for oncology nurses in family history collection and assessment has been proposed.

Cancer genetics requires a shift in focus from the traditional nursing role. Oncology nurses have a patient-centred approach and well developed skills with respect to care of the patient; genetics requires the consideration of the family. Not only is information about the extended family required for assessment, but information given to patients may be directly relevant to, or impact on, other family members.

*Time allocations are somewhat arbitrary as there was overlap between all topics.

members. Consequently, issues of confidentiality, disclosure, and autonomy are complex, and discussion needs to be based upon sound genetic knowledge and principles.

We developed a 16 week (60 hour) course entitled “Cancer Genetics Resource training course” designed to enable oncology nurses to assess a person’s category of inherited cancer risk, facilitate appropriate referral, and identify psychosocial issues.

Course development
The philosophical basis of the course was that dissemination of information and development of skills throughout the health sector would increase accessibility of appropriate services to families. Specifically, educating health professionals about cancer genetics will assist in identification of high risk families and facilitate risk management of those in the low and moderate risk categories. The graduates will be able to assess a family’s inherited risk category, facilitate referral to the relevant services, explore expectations of services, and provide brief counselling for issues such as anxiety and/or grief which may serve as a barrier to acceptance of a referral by the family members.

The course syllabus was developed based on feedback from a focus group comprising oncology nurses and in conjunction with the Anti-Cancer Council of Victoria. It was publicised through the local Oncology Nurses Society, major hospital oncology day centres, and focus group participants. The number of participants was limited to allow effective counselling skills training. Participants were all working in oncology and able to apply the course content in their work. After interview, 10 were accepted from various areas of oncology (education (1), palliative care (1), breast care support (2), cancer help line (2), research/registry (1), wards (3)). Six participants were subsidised by their employing hospital, indicating institutional support and recognition of the course.

Syllabus
Our experience in running workshops in cancer genetics emphasised a diversity of experience and a lack of familiarity with basic genetic concepts. Consequently, participants in the Cancer Genetics Resource training course were expected to complete a basic genetics workshop (12 hours) at the beginning of the course to ensure all had sufficient understanding of key genetic terms and concepts, including ethical issues.

In developing the core syllabus, we focused on skills that nurses could incorporate into their work. Graduates of the course would undertake counselling low and moderate risk families regarding their inherited risk and refer high risk families for specialised counselling. Detailed information about specific cancer predisposition genes, such as the mismatch repair genes, was therefore considered less important than a general understanding of the role of genes in cancer predisposition.

A syllabus was structured in three modules: Counselling Skills (six sessions), Science and Genetics of Cancer (six sessions), and Practice and Perspective (four sessions). Each session was of three hours’ duration.

Counselling Skills
The ability to explore issues underlying a person’s concern about their history is essential in determining the services best able to meet a family’s information and psychosocial needs. Questions by family members are often triggered by a recent critical event (for example, diagnosis, death, or an anniversary) and the emotions engendered by these events may affect the family member’s acceptance of appropriate services.

Areas covered are outlined in table 1. Skills and issues were explored through discussion and role play. The nurses felt comfortable with the “task based” approach necessitated by their usual work and showed a desire to “fix it”. The ability to live with uncertainty, necessary in so many areas of genetics, created problems for participants and was explored further in tutorials by a psychologist with extensive experience in education and supervision.

Cancer: Science and Genetics
This module was designed to enable participants to elicit and distinguish information relevant to family history assessment, to establish the inherited risk category, and identify people whose surveillance was insufficient. The course outline is presented in table 2. The majority of the tutorials focused on risk assessment for the common cancers (breast, bowel, gynaecological, and melanoma). Each was divided into two parts, the first being an overview covering incidence, benign and malignant conditions, inherited conditions, and surveillance. The second part was skill based, with participants assessing case studies. The tutorials relating to fundamental principles of cancer genetics were designed to provide participants with sufficient information to correct common misconceptions, but not to provide detailed genetic information to a patient. Tutors were medical specialists in the field associated with Familial Cancer Clinics. This had the additional benefit of increasing the familiarity and accessibility of participants to key practitioners in the area.
PRACTICE AND PERSPECTIVE

This focused on incorporation of the previous modules into routine work (table 3), including discussion about the participants’ individual workplace situations and challenges. Three common themes emerged. The participants had particular concerns about (1) raising the issue of familial cancer with people who were at high risk but had not indicated any interest in their genetic status, (2) raising the issue of referral with the clinician responsible for care, and (3) the potential increase in workload and need to document the work performed in this area.

Assessment of participants

A criterion referenced approach to assessment was adopted. Participants were expected to show the required level of competency by completing set assessment tasks. If the necessary standard was not achieved, further study was required and competence reassessed until proven.

In the Cancer Genetic Resource course, the ability to determine inherited risk category accurately and competency in deciding the appropriate course of action were assessed. Three assessment strategies were used. The tutor for the counselling module evaluated the involvement and ability shown by the participants during the counselling tutorials. The other modules were assessed by a written examination comprising case studies, family history assessment, and construction of an accurate family tree. This examination was open book, as participants would be expected to access relevant information and resources in their own workplaces rather than rely on memorised information. Each participant was informed of areas of weakness identified by the examination and was then expected to show sufficient skill in that area. Finally, all participants conducted an “in service” training session at their workplace to educate their colleagues about application of their skills.

Evaluation of the Cancer Genetic Resource course

The course was evaluated by the students at the conclusion of each module, at the conclusion of the course, and six months after completion. The participants evaluated a number of parameters, including module content, teaching quality, applicability, expectations fulfilled, and practice of skills. Some parameters were assessed by open questions, but the majority were assessed by Likert scales. Those scores assessed by Likert
A questionnaire was completed by supervisors six months after the course ended. One person had changed jobs during the six month period. Of the remaining nine, eight supervisors indicated that the graduates had incorporated new skills in their work and would recommend the course to other nurses. The remaining one had not observed any change, although the participant herself felt that she had been able to apply her new skills.

**Future directions**

The success of the course in meeting its aims was indicated by (1) the accuracy of the participants' family history assessment, (2) the sixfold increase in the number of participants facilitating referral, and (3) the assessment by participants and supervisors of the applicability of the skills learnt. We conclude that completing a skills based course improves assessment and appropriate referral of those who may be at risk of familial cancer.

Further evaluation is required to assess the extent to which learned skills have been applied and the effectiveness and appropriateness of counselling provided by the graduates. The possibility of holding a full time, intensive, two week course, enabling easier access for non-metropolitan nurses, has been considered. This benefit needs to be weighed against the reduced opportunities for the nurses to apply skills and reflect on their practice between tutorials.

Our course focuses on recognising and meeting the needs of families at low and moderate risk, which constitute the majority of patients and families encountered by oncology nurses. In contrast many training programmes appear to focus on high risk families.11 Diverse roles for oncology nurses in cancer genetics have been proposed11 17 and it is reasonable to expect that different programmes will be required to meet the varying educational needs of these roles.

In time the role of a “Cancer Genetics Resource Nurse” may evolve into a dedicated position, distinct from, but complementary to, the role of Genetic Counsellors working with high risk families in Familial Cancer Centres. This role need not be confined to oncology nurses. With this form of training, social workers would be well placed to elicit concern regarding family history and counsel accordingly. The Cancer Genetic Resource course can be readily adapted for allied health staff or medical professionals.

Participation in preconceptional carrier couple screening: characteristics, attitudes, and knowledge of both partners

L Henneman, I Bramsen, H M van der Ploeg, H J Adèr, H E van der Horst, J J P Gille, L P ten Kate

Editor—Couples in which both partners are carrier for a particular autosomal recessive disease, such as cystic fibrosis, Tay-Sachs disease, or thalassaemia, have a 1 in 4 risk for each child to have this disorder. Population carrier screening programmes aimed at the identification of carrier couples make it possible to inform these couples about their risk and about the reproductive options that are available. Before beginning any genetic screening programme, it is important to assess community interest in screening.1

It is well known that the way in which carrier screening is offered and the timing, for example, during or outside pregnancy, determines participation in screening and the reasons for participation. Screening offered face to face with the possibility of immediate testing gives high uptake rates, whereas offers made by mailed invitation or poster announcements attract little interest.2,4

Most of the data on motives for participation have been obtained from programmes offering carrier screening during pregnancy.7–11 In these studies, a high interest in screening was reported, although it has been argued that testing during pregnancy is often accepted just because it is offered.10 The decision to participate was mostly made by women, who were often initially tested without discussing it with their partner. Anxiety has been reported among those who are tested positive, while waiting for their partner’s results.11,12,13 It can also cause distress when the partner is not available or does not want to be tested.14 Furthermore, prenatal screening leaves limited reproductive options for a carrier couple and might impose time constraints when decisions about a prenatal diagnosis have to be made.20

Offering carrier screening outside pregnancy shows lower participation rates when no pregnancy is planned, but interest is higher when there are plans for having children (preconceptional).4,7–21

This study focused on the preconception period as the time for screening and considered couples as the screening unit. Determining why some couples participate in a preconceptional carrier screening programme while others decline provides insight into the desirability of screening. It may also give some indications of how to improve accessibility to screening for those who are interested. To investigate this, couples can be directly asked for reasons why they decided (not) to participate. In addition, determining differences in individual variables and attitudes between participants and non-participants can be used to explain participation. Early theories on health related behaviour suggest that intention to take a preventive health action is likely when people (1) view themselves as susceptible to the condition, (2) consider the disease to be serious, (3) perceive high benefits of the health action, and (4) perceive few disadvantages in undertaking it.22 These four components are the earliest constructs of the Health Belief Model (HBM), which has been considerably expanded, as was reviewed by Janz and Becker.21 The present study focused on a select group of variables derived from the HBM. This model was chosen because of its applicability to predicting behaviour towards voluntary action, such as carrier screening.

In this study, the determinants of participation in preconceptional cystic fibrosis (CF) carrier couple screening was investigated, focusing on the characteristics and attitudes of
both partners. The study was carried out within the framework of a large project on the feasibility and desirability of CF carrier screening in The Netherlands. It was designed to address the following research questions. What is the main reason why couples choose to participate or choose not to participate in carrier couple screening? Are there HBM related factors associated with participation among eligible couples invited for screening?

**Subjects and methods**

**PROCEDURES**

Participating and non-participating couples were recruited from a feasibility study of preconceptional CF carrier couple screening in The Netherlands. Screening was offered to couples who were considering a pregnancy in the future, by five general practices, between May 1997 and June 1998. In total, 5414 people, aged 20 to 35 years, received a letter of invitation signed by their general practitioner (GP). GPs were asked to exclude patients with fertility problems or psychosocial problems from the mailing list to avoid any possible emotional disturbance of these people by the invitation. The letter invited couples, interested in screening, to attend a 45 minute educational session at a nearby location on two evenings in one week. The letters were non-directive, did not encourage couples to participate, and mentioned that this was a scientific study on interest in participation. Both partners were asked to be present. Enclosed with the letter was an information leaflet. The leaflet described the clinical and genetic aspects of CF, carrier prevalence in the population, the implications for the couple of a positive carrier screening test, and how testing is conducted, including information about the imperfect sensitivity of the test (the test sensitivity in this study was approximately 87%). A member of the research group (LH) organised the educational sessions. At the session, attendees were given more detailed information, and an outline of possible advantages and disadvantages of screening was presented. At the end of the session, couples were offered the carrier test, which would be performed by mutation analysis on a mouthwash sample. All of this was offered free of charge. Exclusion criteria for the participation of couples were: pregnancy, a positive family history of CF, and age younger than 18 years. Both partners of participating couples provided a mouthwash sample. If only one partner was able to attend the session, a kit was provided in which the mouthwash sample of the other partner could be collected at home. After the educational session, couples were given an informed consent form to take home and were asked to return it by mail within one week. The Medical Ethical Committee of the academic hospital Vrije Universiteit in Amsterdam approved the study protocol.

**UPTAKE**

To determine the uptake of screening, a non-response survey by telephone was performed to estimate the percentage of eligible persons in the invited population. Eligibility was defined as having a steady relationship and planning to have one or more children with the partner. A random, age stratified sample of those who did not respond to the initial invitation for screening, that is, did not attend the educational session, was contacted by telephone on different evenings during the week. Other random subjects replaced those who did not answer the telephone after three calls until samples of approximately 10% (n=387) in every practice were reached. Respondents were asked whether they had received the letter of invitation from their GP, whether they were interested in screening, and whether their situation conformed to that of the target population. The non-response telephone survey showed that 19.6% (76/387) of these invited subjects were eligible for participation. In the calculation of uptake rates, the responses of subjects to the invitation were considered, and not the responses of couples, since invitations were sent to individual people and some partners did not receive an invitation because their age group was not included or because they had a different GP. Subjects whose mail was returned by the post office as undeliverable (n=99) were excluded from the study. In total, 108 subjects (related to 79 couples) responded to the invitation for screening. The response therefore was 2% of the total population (108/5315) and 10.4% of the eligible (target) population (108/1042). Seventy-eight couples consented to participate in the test (78/79, 98.7% participation) after the educational session.

**COMPARISON OF PARTICIPANTS AND NON-PARTICIPANTS**

To determine factors influencing the decision to accept the test, differences between consenting couples (participants) and a sample (see below) of eligible couples who did not attend the screening session, identified through the non-response telephone survey (nonparticipants), were investigated. Data were gathered by means of questionnaires that were identical for both partners and both groups. Questionnaires were administered to all attendants at the beginning of the educational session. Each partner in a couple was asked to complete the questionnaire individually without consulting the other partner. Of the 78 participating couples, 76 completed the questionnaire.

Non-participants who confirmed during the non-response telephone survey a desire to have children with their partner, that is, they were eligible for participation (n=76), were asked whether they and their partner would be willing to complete the questionnaire and return it by mail. Of these 76 non-participants, six did not wish to take part in the study. In total, 76% (53/70) of the non-attending eligible couples returned the questionnaire. Those who did not return the questionnaire (n=17) had previously reported by telephone that their main reason for non-participation was lack of time. Eventually, 76 participating and 53 eligible non-participating couples could be compared.
QUESTIONNAIRE DESIGN
The questionnaire was developed and tested for homogeneity specifically for this study. Subjects were asked, in an open ended question, to indicate the single most important reason for participating or not participating in the screening. In addition, they were asked to report which partner (both partners, man, or woman) had influenced the decision most, and their agreement over the final decision (both agree, partner disagrees, or I disagree). Furthermore, the questionnaire assessed certain components of the Health Belief Model (HBM) including the following:

(1) Sociodemographics
Subjects provided information on age, gender, marital status, highest level of education, number of children, and religiousness. Couples were also asked to indicate whether a pregnancy was planned in the short term (within the next two years) or in the long term (after the next two years).

(2) Familiarity with the disease
Familiarity with the disease was derived from the response to the question: had you heard about the disease cystic fibrosis before receiving the invitation for screening?

(3) Knowledge of the disease
This consisted of seven multiple choice questions, assessing the level of understanding of the medical and genetic aspect of CF and carrier testing. A response of “don’t know” was scored as an incorrect answer. The number of questions answered correctly was calculated as a sum score. The answers to the separate questions were also considered.

(4) Health locus of control
The validated subscale of the Multidimensional Health Locus of Control scale with the locus dimension “internal control” was used to indicate the extent to which subjects perceived their behaviour as responsible for their own health (IHLC). According to this model, a person is more likely to engage in healthy behaviour if he or she has a strong internal locus of control. The subscale consists of six items, and the answering format was a six point Likert scale (completely agree (1) to completely disagree (6)). A total sum score was computed for each subject, with high scores indicating a higher likelihood of engaging in healthy behaviour. Cronbach’s $\alpha$ for IHLC on the data was 0.76.

(5) Perceived discomfort
The respondents were asked to indicate the extent to which they agreed that screening requires too much of their time and effort (completely disagree (1) to completely agree (5)).

(6) Constructs of HBM
The questionnaire included 14 items specifically addressing carrier screening, to measure perceptions concerning carrier testing (see Appendix). The newly developed constructs were derived from the four basic HBM dimensions: (1) perceived risk of being a carrier (couple) and having a child with CF (“Perceived susceptibility”, three items), (2) perceived severity of the disease and the burden of treatment of a child with CF (“Perceived seriousness”, three items), (3) benefits of testing (“Perceived benefits”, five items), and (4) perceived barriers related to screening, such as worries about testing, the perceived impact of carrier status, and the perception that other people will look differently at them when they are identified as carrier (“Perceived impact barriers”, three items). For “Perceived susceptibility”, respondents were asked to indicate the extent to which they agreed with each statement on a five point Likert scale (completely disagree (1) to completely agree (5)). Principal axis factor analysis with varimax rotation was performed to verify that the items loaded on the four factors of the HBM. Subsequently, a reliability analysis was performed on each scale to determine whether all items contributed to the internal consistency of the scale. Summing up items results in a single measure for three subscales with good reliability: “Perceived susceptibility” (Cronbach’s $\alpha=0.83$), “Perceived benefits” (Cronbach’s $\alpha=0.90$), and “Perceived impact barriers” (Cronbach’s $\alpha=0.64$). For “Perceived seriousness”, the items (n=3) were considered separately, owing to the low internal consistency of the total scale.

DATA ANALYSES
To answer the first research question, the answers of couples to the open ended question about the main reason for participating or not participating in screening were coded into general categories. Before trying to answer the second research question, it was necessary to determine whether the data of both partners should be included as a pair, because both the man and the woman of each couple completed a questionnaire. To investigate this, the responses to questionnaires of both partners were compared, using McNeMar non-parametric tests for categorical data and paired $t$ tests for continuous data. Since the sociodemographic status was highly correlated between the partners within a couple, data of only one randomly selected partner were included in the bivariate analyses comparing participants and non-participants. For all other variables (2) to (6), at first the median split of the sum scores was taken, which resulted in subjects with low scores and subjects with high scores (knowledge low (0-3), high (4-7); IHLC low (6-23), high (24-36); susceptibility low (3-9), high (10-18); benefits low (5-19), high (20-25); impact barriers low (3-6), high (7-14), and separate items (discomfort and seriousness) low (1-3), high (4-5)). Paired data analyses showed that in the responses to these variables, there were moderate to low associations between partners in a couple, indicating that both partners provide different information. Therefore, it was not possible randomly to select one partner of the couple for the analyses. In addition, since the attendance of a couple at the
Results

Main reason given for participation and non-participation

Among the 76 couples who decided to attend the educational session and consented to CF carrier testing, the decision was taken jointly in 85%, while 15% reported that the woman had more influence on the decision to participate. Nevertheless, none of the couples reported disagreement on the final decision. The main reason given by couples for taking the test was that they wanted to know whether they were a carrier couple with a high risk of having a child with CF (97%). The other couples (3%) gave no specific reasons for taking the test. The reasons non-participants gave (in their own words) for not participating in screening varied, but the most commonly stated reason for not attending the educational session was “lack of time” or “forgot to attend the educational session” (53%, n=28). Other reasons given were that “the test results would not influence our attitudes towards family planning” (21%, n=11). Furthermore, 15% of the couples were not interested in testing because they were “not concerned” (n=6) or they had “never heard of CF” (n=2). Five percent reported “testing would make us too anxious”. The answers of most partners in a couple could be placed in the same category. However, in three couples (6%), the partners showed disagreement; the women reported that they were interested in screening but they declined the test because their partners were reluctant to participate.

Factors associated with participation

Sociodemographics of participants and non-participants, both men and women, are shown in Table 1. Within the couples included in the study, no statistically significant differences were found between men and women with regard to educational level, time period in which children were planned, and religiosity. The men were significantly older than the women in both participating and non-participating couples. In general, within a relationship, men are older than women in The Netherlands. In bivariate analyses, no associations could be shown between participation and the variables age, marital status, level of education, number of children, the time period for planning children, or religiosity.

While the sociodemographics for both men and women within the couples were highly comparable, paired data analyses showed that in the responses to the other variables, such as familiarity with CF, knowledge of CF, and perceptions with regard to carrier screening, there were differences between partners. Therefore, data of both partners were included in the subsequent analyses. Table 2 shows the bivariate associations between components of the Health Belief Model and participation in screening for the three different concordance groups (“High-High”, “High-Low”, “Low-Low”). Participating couples scored higher than non-participating couples on the knowledge questionnaire, and higher on the internal health locus of control (IHL) scale and perceived higher benefits of testing. In addition, participating couples were more likely than non-participating couples to perceive low discomfort of screening and low impact barriers to screening. No associations were found between participation in screening and familiarity with CF, perceived susceptibility, or the items on perceived seriousness. Furthermore, no differences in responses were found between the five general practices that participated in offering the screening.

The relevant components found in the bivariate analyses were entered into one multiple logistic regression model simultaneously. Coefficients, odds ratios (OR), 95% confidence intervals (95% CI), and p values for this model are presented in Table 3. Perceived discomfort and perceived benefits appeared to be the strongest predictors for participation in screening. Couples in which both partners received low discomfort of screening were more likely to participate.

Educational sessions. These couples may differ in their attitude towards testing from the other non-participating couples. To analyse this, couples who did not attend were divided into two subgroups: (1) those who reported that they had no time or had forgotten to attend, but were possibly interested in screening (“lack of time”, n=28), and (2) those who did not attend for other reasons (“other reasons”, n=25). Bivariate analyses of the variables (1) to (6) showed that only one variable was associated with reporting “lack of time”. In non-participating couples reporting “lack of time”, it was more likely that both partners perceived high benefits of screening than in non-participating couples reporting “other reasons” (50% v 16%) (OR=8.7 (2.0–37.7)). In addition, two-thirds of these couples perceiving high benefits and reporting “lack of time” had high knowledge scores.

Of all non-participants, 76% supported the view that genetic carrier testing for CF should be offered to all couples planning to have children, 15% did not favour this opinion, and 9% were not sure. Among those who reported “lack of time”, only two respondents were opposed to offering screening in the general population.

PARTICIPANT AND NON-PARTICIPANT KNOWLEDGE

With regard to more detailed knowledge of CF, a comparison was made of correct answers of participants (before the educational session) and non-participants to five multiple choice questions on the knowledge questionnaire. The answers to these questions could all have been found in the information leaflet, which was sent with the letter of invitation for screening. Participants were significantly more likely than non-participants to be aware of the most important symptoms of CF (64% v 32%), to know that carriers do not need to have a family history of CF (83% v 69%), to recall the risk of being a CF carrier (61% v 39%), and to...
understand that carriers of CF would not develop CF related health problems (66% v 41%). There was no association between knowledge scores and level of education. In both groups, women scored higher on the knowledge questionnaire than men. In addition, more women than men had previously heard of CF.

**Discussion**

In this study, factors associated with participation in preconception carrier couple screening were assessed. The results suggest that couples who participated in the CF carrier screening programme, as opposed to those who did not, perceived lower discomfort from screening, perceived higher benefits, perceived lower impact of the consequences of screening, knew more about CF, and perceived their own behaviour to be responsible for their health. Overall, the results were more pronounced when partners had similar perceptions. The main reason given for not participating in screening was lack of time to attend the educational session. The results showed that couples who lacked the time to attend perceived more benefits from screening than couples reporting “other reasons” for non-participation.

As expected, higher perceived benefits of the test were associated with more participation in screening. Benefits from testing reflect the importance couples attach to knowing their chances of having a child with CF, which was also found to be the most frequently reported reason for participation in screening. It also reflects the expectations of the couples that they will have more reassurance and that the test results will help them to make decisions about having children. Higher awareness of the benefits of screening may increase the acceptance and participation of couples in screening. In 34% of the non-participating couples, the perception of the discomfort of screening was high for at least one partner. These couples will probably only participate if screening takes less of their time and does not require an extra visit.

The results also suggest that those who perceive low impact barriers, such as the impact of carriership on their general health status and the perception that other people will look differently at them, are more likely to accept screening. Only 41% of all non-participants stated correctly that carriers of CF would not develop health problems resulting from their carrier status. These results suggest that anxiety about screening and the burden of carrier status are partly based on misconceptions owing to lack of knowledge.

Knowledge of CF was also a predictor for participation in screening, although this is probably more a reflection of the interest couples have in screening and reading the leaflet before attending the educational session than knowing about CF before the invitation for screening. Nevertheless, inadequate understanding could lead to increased anxiety, and therefore result in non-participation. Bernhardt et al stated that better baseline understanding of human genetics in the public might provide a basis for understanding genetic screening tests and interest increase in learning about screening tests.

The percentage of respondents who were familiar with CF is comparable with the percentages in the Dutch population in general, in which 60% know about the disease and 15% know somebody with CF. Familiarity with the disease was not associated with participation. This could be explained by the fact that people may have heard about CF, but do not know the clinical implications or the hereditary pattern of the disease. Possibly therefore, this variable was not a motivating factor in participation.

Studies have shown that people are more likely to participate in screening if they consider themselves susceptible to being a carrier or to having an affected child. This is in contrast with the findings of the present study, in which no association was found between perceived risk and participation. Most respondents thought it very unlikely that they would be a carrier or that they would have a child with CF. The percentage of respondents knowing the carrier risk was 61% in the participants and 39% in the non-participants. Again, this might imply that non-participation is partly based on lack of knowledge and the assumption that CF is not very common. The question remains as to whether a more accurate understanding of actual risk might have led to a different perception of risk, which would influence participation. A previous study has shown that perceived risk, rather than actual risk, influences the participation of women in prenatal screening tests. Presumably, couples participate because they want to be reassured that their risk is low, and not because there is a chance of their being carriers or having a child with CF. This is supported by the findings of Loader that the desire for reassurance of a low risk of having a child with CF was mentioned twice as often (50.6%) as the intention to avoid having such a child (27.8%).

Other studies have also reported the lack of an association between perceived seriousness of the disease itself and participation in screening. In the present study, the burden of the disease and the burden of a child with CF was perceived as high for most respondents, whereas the impact of treatment was perceived as moderate to low. This suggests that respondents perceive CF as a very serious disease, but think they can cope with a sick child in practice. In the present study, no influence of the level of education on participation was found, which is in contrast with the findings of other studies. Furthermore, already having children was not found to be a reason to decline screening, suggesting that the couples understood this aspect of inheriting CF. Overall, 45% of the couples were married, as expected from this age group in the Dutch population.

The effect of factors predicting participation in screening was more pronounced when couples shared their views. To our knowledge, only one other study described the agreement of
husband and wife in predicting participation in a carrier screening programme. In this study, it was found that the combined beliefs of couples increased precision in the prediction of who will participate in screening for Tay-Sachs disease.

In the present study it was stressed that both partners should attend the educational session to receive the same information, on which subsequent decision making could be based. Of all participating couples, 15% reported that the decision to accept screening was merely the woman’s decision, whereas 6% declined because the male partner did not wish to participate. The results also showed that women had heard about CF more often than men and knew more about the disease. Overall, these results are consistent with the findings of other studies, that is, that interest in testing is greater among women than among men. This may reflect the greater concern and responsibility in reproductive decisions felt by women. Future analyses of additional data will be performed to determine whether gender differences in the response to the test results can be found, as has been reported in other studies.

Lack of time was the most frequently reported reason for non-participation. The invitation to attend the educational session on two evenings in one week was sent 14 days in advance. This might have been too short for people who already had other appointments on these evenings. Moreover, it has been found that when screening is offered a second time, on more evenings, or when people can make their own appointment, for example with their own GP, participation increases (Henneman et al, in preparation). Although not reported, another reason for non-participation might be that couples prefer personal counselling instead of attending a general educational session with other couples. In a study carried out by Clayton et al, non-pregnant couples showed lack of interest in carrier screening. Reluctance to participate was ascribed to worries about factors such as insurability, being at risk, what they would need to learn, abortion, and religious beliefs. However, the authors believe that lack of interest in that study might also be explained by the mode of invitation, letters placed in pockets on signs and not personally addressed to those who were offered screening. Mode of invitation has been found to be the most important factor influencing acceptance. Invitations that were more personal might have increased interest in that specific screening programme. In prenatal carrier screening, unwillingness to terminate an affected pregnancy was mainly found to be the most frequently reported reason to decline screening, although lack of time has also been reported.

The uptake of the pre-educational screening session of couples who planned to have children was 10.4% in the present study. This uptake is not high, compared with other screening programmes offered before pregnancy and during pregnancy. However, the authors are of the opinion that uptake rate is not the most important determinant, if not for economic reasons, of the desirability of screening. Yet, knowledge about motives and barriers for participation is important. As Martin also emphasised, one of the key research questions for the next 10 years should be to find the best way of offering tests to achieve informed choice. In the present study, the main reason couples gave for participation in the screening was to find out whether they were at high risk of having a child with CF. None of the couples reported that they participated in the screening because they were told to do so by their GP or that they felt that they could not refuse. These results suggest that because of the time and effort needed for participation, couples were stimulated to make a decision based on the conviction that screening is important, and not just because it is offered or strongly recommended, as was argued for opportunistic screening programmes with high uptake rates.

For this study, new scales based on the Health Belief Model (HBM) were developed to evaluate the response of couples to CF carrier screening. Several other components of the HBM, that were not addressed in the present study for practical reasons, may also be important, such as interpersonal interactions and mass media communications, and the influence of psychological defence mechanisms, such as avoidance behaviour. There has also been more general criticism of the model, like other rational choice theories, that is, that it provides an idealised view of how decisions should be made and that it gives insufficient attention to emotion in decision making and the role of cultural standards and values. However, the HBM provided more insight into the motives and barriers reported by couples who were offered carrier screening. In addition to HBM related variables, other variables are also considered to be important in affecting participation in carrier screening, such as tolerance of test uncertainty.

This article specifically addressed the participation in preconceptional CF carrier screening in The Netherlands. Differences between other screening programmes and other countries will exist, but many similarities are evident, and the results of this study can be used in the development of other programmes. Preconception screening was chosen because it provides a maximum number of reproductive options for identified carrier couples and involves a minimum of (time) constraint. Furthermore, there are three other reasons why preconception screening is highly applicable in The Netherlands. Firstly, prenatal screening is difficult for practical reasons, because many pregnant women visit a clinic late in their pregnancy. Secondly, preconception screening meets the requirements formulated by the Committee for Genetic Screening of the Dutch Health Council, whereas prenatal screening does not. Thirdly, there are a large number of planned pregnancies in The Netherlands (85-90%), creating an ideal situation for contacting couples before conception. These reasons may also be valid for other countries.
Appendix

Constructs of the Health Belief Model: subscales and items with good reliability and associated α (n=3) and separate items of subscales with low reliability (n=1)

**Subscales:**
- Perceived susceptibility (Cronbach’s α 0.90)
  - Estimated likelihood of being a CF carrier
  - Estimated likelihood of being a CF carrier couple
  - Estimated likelihood of having a child with CF
- Perceived benefits (Cronbach’s α 0.83)
  - Carrier testing gives me more reassurance
  - It is important for me to know if I am a carrier
  - It is important for me to know my risk of having a child with CF
  - The test results will help me to make childbearing decisions
  - Carrier testing should be offered to all couples who are planning to have children
- Perceived impact barriers (Cronbach’s α 0.64)
  - If I had carrier testing, I would feel worried
  - If I were a carrier, I would feel less healthy
  - If I were a carrier, people would look differently at me

**Separate items:**
- Perceived seriousness of disease
  - CF is one of the worst diseases there is
  - I would find it hard if my child had CF
  - I would find it hard to give my child the treatment

*Cronbach’s α < 0.40

addition, preconceptional screening can be considered for a number of other reasons, as has recently been suggested for Tay-Sachs disease and haemoglobin disorders. For example, in the UK, prenatal screening for haemoglobin disorders is recommended as a routine practice, although it has been shown that the present practice does not always meet the needs for early information and leads to the late recognition of risk. Moreover, at the beginning of a thalassaemia screening programme in Sardinia in the mid 1970s, the largest category of participants consisted of pregnant women, whereas the number of couples without a pregnancy is currently increasing. In other countries, however, cultural differences influence the approach to carrier screening. For example, screening is offered premaritally to communities of Orthodox Jews, to prevent the marriage of two carriers of recessive disorders.

In this study, interest in preconceptional CF carrier screening, requiring time and effort to participate, is shown, both by the actual participation of couples and by the perceived benefits of screening of couples who did not participate. The results of the study could be used as a model for other screening programmes. Lack of time to attend the educational session was found to be the main influence on participation in carrier screening by non-pregnant couples. However, the results suggest that these couples have positive attitudes towards screening and will attend when screening is offered more conveniently. The results also indicate that participation is influenced by “psychological” barriers, possibly caused by an incomplete understanding of the consequences of carrier testing. These barriers could be removed by providing more clear information about the meaning of carrier status and by increasing public awareness. In addition to participation in screening, the psychological and cognitive consequences of screening are being investigated.

The authors thank the participating general practitioners for their cooperation in this project, and especially Henk de Vries. This project was supported by the Vrije Universiteit Medical Centre Amsterdam and by grant No 2827030 from the Netherlands Health Research and Development Council.

Functional characterisation of mitochondrial tRNA Tyr mutation (5877G→A) associated with familial chronic progressive external ophthalmoplegia

Ko Sahashi, Makoto Yonedo, Kinji Ohno, Masashi Tanaka, Tohru Ibi, Kentaro Sahashi

EDITOR—Chronic progressive external ophthalmoplegia (CPEO) is a common clinical manifestation of mitochondrial cytopathies characterised by ophthalmoplegia and ptosis. 1 Approximately two-thirds of CPEO patients harbour a large, heterogeneous, mitochondrial DNA (mtDNA) deletion. 2 Some other CPEO patients carry a point mutation in the mitochondrial tRNA genes. Twelve point mutations in six mitochondrial tRNA genes have been reported to date in association with CPEO (Mitomap at http://www.gen.emory.edu/mitomap.html). Among the 12 mutations, 5703C→T in the tRNA Tyr gene has been functionally characterised. 3 Here we report functional analysis of 5877G→A in tRNA Tyr identified in a patient with CPEO using p cells that lack mtDNA.

A 45 year old woman had moderate degrees of ptosis, external ophthalmoplegia, and proximal muscle weakness from the age of 28. She had no sensorineural hearing loss, ataxia, pigmentary retinopathy, hypogonadism, or mental retardation. She had episodic diarrhoea of unknown aetiology. An ECG showed atrioventricular conduction block, while EEG, brain CT, and brain MRI showed no abnormalities. An exercise loading test of 15 watts for 15 minutes on a bicycle ergometer raised her serum lactate from 6.9 mg/dl to 24.0 mg/dl (normal, less than 18.0 mg/dl), and her serum pyruvate from 0.6 mg/dl to 1.4 mg/dl (normal, less than 1.3 mg/dl), thereby increasing the lactate to pyruvate ratio from 10.7 to 17.1 (normal, less than 13.8). A biopsy specimen obtained from the biopsies brachi showed 40% ragged red fibres and 0.7% cytochrome c oxidase negative fibres.

Mutation analysis of muscle mtDNA was briefly described previously (patient 2 in Ozawa et al ). Determination of the entire mtDNA sequence showed 34 nucleotide changes; 33 were homoplasmic and were observed in 274 controls with variable frequencies. A 5877G→A transition in the tRNA Tyr gene was homoplasmic and unique to the patient. The ratios of mutant to wild type mtDNA were 73% in skeletal muscle and 0.7% in blood (fig 1B). The 5877G→A mutation is located in the DHU loop of the tRNA Tyr gene (fig 1A). The 5877G base pairs with 5905C in the variable loop (circle in fig 1A) to form the L shaped tertiary structure of the tRNA...
molecule. The 5877G is conserved in 29 of 43 species or in 25 of 28 vertebrates (alignment not shown). The 5877G→A mutation has not been reported in other patients with mitochondrial cytopathies (Mitomap).

Restriction enzyme analysis of blood and umbilical cord DNA of family members showed that the deceased mother, who had ptosis, carried 5877G→A and that two asymptomatic children (a 21 year old son and 19 year old daughter) harbour 5877G→A. Photographs showed that the deceased mother, who had ptosis, and her DNA was not available. The 5877G→A mutation has not been reported in other patients with mitochondrial cytopathies (Mitomap).

Figure 1 (A) Secondary structure of tRNA\(^{\text{Asn}}\) and 5877G→A mutation. A circled C nucleotide in the variable loop (5906G) indicates a residue that base pairs with 5877G to make the L shaped tertiary structure. Short lines in the stems indicate hydrogen bonds linking the paired nucleotides. (B) DdeI restriction analysis of 5877G→A in family members. PCR amplified mtDNA fragments from nucleotides 5681 to 5960 were digested with DdeI, which only cleaves at the wild type 5877G. Closed arrowhead points to a mutant 261 bp fragment. Open arrowheads indicate wild type 178 and 83 bp fragments. A mutant fragment in the patient's blood is scarcely visible in the figure. Arrows indicate the patient. Closed symbols show affected family members. BS, blood spot in the hospital archives from deceased mother; PB, peripheral blood; SM, skeletal muscle, UC, archived umbilical cords of patient's children which had been saved as mementos of birth.

patient’s skin fibroblasts as described elsewhere. We obtained four distinct cybrid clones, H35, H25, H63, and H11, harbouring 0, 3, 39, and 23% of mutant mtDNA, respectively. We measured the oxygen consumption as an indicator for the mitochondrial respiratory chain functions, using a Clark type oxygen electrode. The H35 clone showed the highest oxygen consumption and the H11 clone the lowest (fig 2A). We next measured the viability of cybrids under 95% oxygen on days 3 and 4 by staining cells with 0.15% trypan blue, because we assumed that mutant mtDNA increases the leakage of reactive oxygen species, which in turn exerts cytotoxic effects leading to cell death. Even normal mitochondria convert approximately 1-5% of oxygen into the reactive oxygen species, which results in degeneration of proteins, lipids, and nucleic acids. Similar to the oxygen consumption analysis, H35 showed the highest viability rate and H11 the lowest (fig 2B). Although H63 harboured a higher ratio of mutant mtDNA than H11, H63 showed higher oxygen consumption and higher viability rate than H11. This may be because of the difference in the intracellular distribution of mutant mtDNA or in the total number of transformed mtDNA.

A previously characterised 5703C→T mutation at the anticodon stem of tRNA\(^{\text{Tyr}}\) destabilises the tRNA secondary or tertiary structure and decreases steady state levels of tRNA\(^{\text{Tyr}}\). The present 5877G→A mutation in tRNA\(^{\text{Asn}}\) alters an essential residue to form the L shaped tertiary structure of tRNA. Similarly, seven out of the 11 other CPEO associated point mutations (Mitomap) are at the tRNA stems...
and probably destabilise the tRNA structure. However, four other mutations are at the tRNA loops and their effects on the tRNA structure remain unknown.

The 5877G→A mutation exerts deleterious effects even at 23% of mutant mtDNA, whereas more than 90% of mutant mtDNA is required to show pathogenicity of 3243A→G in tRNA Leu(UUR), which is primarily associated with MELAS.11 Hao and Moraes’ proposed that null or near null mtDNA mutations are associated with muscle pathologies, as exemplified in 5703C→T in tRNA and in mtDNA deletions. On the other hand, less severe mtDNA mutations are associated with central nervous system symptoms, as in the MELAS and MERRF associated mutations.10 That low levels of mutant mtDNA decrease oxygen consumption and compromise cell viability under 95% oxygen in the current studies further supports their hypothesis on phenotype-genotype correlation of mtDNA mutations.

This work was supported in part by the Grants in Aid for General Scientific Research (62570128) to the Ministry of Education, Science, and Culture of Japan. We presented part of the present study in a review article (Nippon Ronsho 1995;35:3263-9).

**Mutation detection in long QT syndrome: a comprehensive set of primers and PCR conditions**

P Syrris, A Murray, N D Carter, W M McKenna, S Jeffery

**Editor—**Long QT syndrome (LQTS) is an inherited disorder which produces arrhythmia and sudden death. The only presymptomatic indication of the disorder is an extended QT interval, in excess of 460 ms.1 However, those with LQTS do not always show this prolongation of QT. There are dominantly and recessively inherited forms of the disease, Romano-Ward syndrome and Jervell Lange-Nielsen syndrome, respectively, the latter also exhibiting severe sensorineural deafness.2,3 About half the familial cases of LQTS are known to be caused by mutations in five ion channel or channel associated genes, with over 90% being associated with potassium channel associated genes, with over 90% being associated with potassium channels.4,5 The sodium channel gene SCN5A is responsible for about 8% of cases with a known gene mutation, while KCNE1 and KCNE2, which code for proteins that associate with KCNQ1 and HERG, both of which code for potassium channels, are the main channel genes.4,6 The sodium channel gene SCN5A is responsible for about 8% of cases with a known gene mutation, while KCNE1 and KCNE2, which code for proteins that associate with KCNQ1 and HERG, respectively, are mutated in 1-2%.7,8 Mutations in KCNQ1 can produce both dominant and recessive forms of the disease, depending on the nature of the mutation.9-12 HERG and SCN5A mutations are dominant, while those in KCNE1 and KCNE2 are recessive.13-16 There are, however, exceptions to these rules.17-18

Mutations have been identified throughout the genes,19-20 although analysis of both HERG and SCN5A has tended to be concentrated on the pore regions owing to the substantial number of exons in both genes. The initial publications on KCNQ1 (formerly KVLQT1) also analysed the pore and surrounding regions, although several groups have now produced primers that cover the entire gene.21 The mutation analysis has been by PCR followed by SSCP, and although laborious, this is still the most commonly used method. Investigation of all the genes has not been possible, mainly because the exact sequence of the PCR fragments amplified by the existing primer sets was not available for SCN5A22 and the published primers for SCN5A, HERG, and KCNQ1 amplified fragments outside the optimum size for SSCP or proved difficult to use.23-24 Larsen et al25 have reported a robust analysis of KCNQ1 and HERG, but this uses an automated capillary SSCP analysis on an ABI 310 with an in house cooling system, which is not available in most laboratories, and SCN5A was not included in this report. To allow extensive investigation of populations potentially at high risk for mutations in genes known to cause LQTS, we have put together primer sets for all five genes, using
Materials and methods

POLYMERASE CHAIN REACTION

The same PCR protocol was initially used in order to amplify all PCR products. Red Hot Taq DNA polymerase and buffers were supplied by Advanced Biotechnologies, dNTPs were purchased from Pharmacia, and primers were made by Genosys-Sigma. PCR was performed using 50 ng of DNA in a volume of 25 µl and the final concentration of reagents was 1 x buffer (20 mmol/l (NH₄)₂SO₄, 75 mmol/l Tris-HCl, pH 8.8, at 25°C, 0.01% (v/v) Tween 20, 1.5 mmol/l MgCl₂), dNTPs (0.2 mmol/l each), 0.2 µmol/l of each primer, and 1.25 units Red Hot Taq polymerase. Amplification was carried out with the use of a Touchdown thermal cycler (Hybaid). Conditions for each PCR product were optimised by varying the annealing temperature and the Mg²⁺ concentration in the PCR reaction. A typical PCR programme (a) comprised the following steps: 94°C for three minutes (one cycle), 94°C for one minute, variable annealing temperature for one minute, 72°C for one minute (35 cycles), 72°C for 10 minutes (one cycle). For several amplifications, a touchdown PCR programme with variable annealing temperatures was used. In that case, the annealing temperature ranged between 70-60°C (b), 70-58°C (c), 65-53°C (d), or 60-50°C (e) depending on the melting properties of the primers. A typical touchdown PCR programme consisted of the following steps: 94°C for three minutes, 94°C for one minute, annealing started at 70°C and decreased by 1°C per cycle, 72°C for one minute (11 cycles), 94°C for one minute, 60°C for one minute, 72°C for one minute (30 cycles), 72°C for 10 minutes (one cycle). Finally, in some cases, amplification conditions given by Splawski et al. were chosen in order to amplify certain KCNQ1 and KCNE1 fragments. These were (f) 94°C for three minutes (one cycle), 94°C for 10 seconds, 58°C for 20 seconds, 72°C for 20 seconds (30 cycles), 72°C for five minutes (one cycle) and (g) 94°C for three minutes (one cycle), 94°C for 10 seconds, 64°C for 20 seconds, 72°C for 20 seconds (five cycles), 94°C for 10 seconds, 62°C for 20 seconds, 72°C for 20 seconds (30 cycles), and 72°C for five minutes (one cycle).

Products that did not amplify satisfactorily were subjected to a different PCR method using HotStar Taq DNA polymerase and following the manufacturer's protocol (Qiagen). In some cases, a PCR additive, Q solution (also supplied by Qiagen), was included in PCR reactions to facilitate the amplification of difficult templates by modifying the melting behaviour of DNA. Amplification conditions, primer sequences, and sizes of amplified products are given in tables 1-4.

Table 1 Amplification conditions, primers, and sizes of PCR products for KCNQ1 coding region. PCR programmes (a-g) are given in Methods. The value following programme (a) indicates the annealing temperature for each PCR amplicon. Primers were taken from Splawski et al. except those with an asterisk which were redesigned.

TTT GAG GC 3'), 13R (5' GTG AGG AGA AGG GGG TGG TT 3') and 15R (5' GCA GGA GCT TCA CGT TCA CA 3'). PCR conditions are given in table 1.

HERG

Primers were taken from Splawski et al14 and Itoh et al.23 The details and PCR conditions are shown in table 2.

SCN5A

Primers first published by Wang et al22 were initially used to amplify all 28 exons of the SCN5A gene. All PCR products were then purified and sequenced. New primers were designed for PCR products with lengths unsuitable for SSCP analysis (approximately >350 bp). Primers and PCR conditions for the amplification of the SCN5A gene are given in table 3.

KCNQ1 AND KCNE2

Primers for amplification of the coding region (single exon) of the KCNQ1 and KCNE2 genes were taken from Splawski et al15 and Abbott et al16 respectively (table 4).

SEQUENCING

PCR products were sequenced using BigDye Terminator chemistry on a 377 ABI PRISM DNA sequencer (PE Biosystems) according to standard protocols.

Results

Using the PCR conditions detailed in tables 1-4, PCR consistently yielded clean products for all LQT fragments. For KCNQ1, 17 PCR fragments were produced as exon 1 was divided into two separate amplicons. For HERG, 19 PCR fragments were amplified as exons 4, 6, 7, and 12 were split into smaller amplicons. Four new primers were designed for KCNQ1, and existing sequences were used for HERG. However, in the former case, 10 primer sets needed changes to suggested PCR protocols, while for HERG this was necessary for all amplicons, and primers from two sources17,23 had to be used to obtain optimal results. In the case of SCN5A, the whole coding region was amplified with the use of 34 PCR fragments. Exon 1 was excluded as it corresponds to the 5' UTR part of the gene and similarly part of exon 28 was not amplified as it is the 3' UTR. Initially, all PCR fragments amplified using the existing SCN5A primers22 were sequenced in order to determine their

www.jmedgenet.com
base composition. This was considered necessary as (1) many fragments were of unsuitable size for SSCP analysis and (2) the intronic sequence surrounding all SCN5A exons was completely unknown with the exception of the splice junctions which were determined previously.22 Twelve new primers yielding smaller PCR amplicons were designed for exons 2, 7, 8, 14, 16, 23, 25, and 28 while exons 12, 16, 17, and 28 were subdivided into several PCR products because of their large size. For KCNE1 and KCNE2, existing primer sets were used for the amplification of the whole coding region of these genes which is contained in a single exon.16 19 However, we reduced the number of PCR fragments needed from three to two. For KCNE1, the two amplified fragments correspond to fragments 1 and 2 (264 and 231 bp respectively) reported by Splawski et al.19 These completely cover the coding region of this gene and therefore there was no need for a third fragment. With regard to KCNE2, we combined the forward primer from fragment 1 and the reverse primer from fragment 2 quoted by Abbott et al.16 to create a new PCR amplicon of 293 bp. A second PCR

amplon was produced with the primers which Abbott et al.16 used for fragment 3 in their study (213 bp).

SSCP analysis using the methods described earlier produced clear bands for all PCR amplons. In many cases, depending on their size, PCR products of two or more exons were loaded onto the same lane and resolved simultaneously on an SSCP gel, for example, KCNE1 exons 2, 11, and 15 or SCN5A exons 11, 12, and 15.

A number of samples from sudden death cases and controls (healthy unrelated subjects) were used to evaluate the efficiency of our methods. SSCP analysis of over 60 samples for KCNQ1, KCNE1, and KCNE2 identified six polymorphisms in the first two genes. These were 1086 C>A V308V, 1638 G>A S546S, found two SNPs at amino acid positions 546 and 64228 and there is no need for SSCP analysis using the methods described in this study, for example, KCNE1 exons 2, 11, and 15 or SCN5A exons 11, 12, and 15.

A number of samples from sudden death cases and controls (healthy unrelated subjects) were used to evaluate the efficiency of our methods. SSCP analysis of over 60 samples for KCNQ1, KCNE1, and KCNE2 identified six polymorphisms in the first two genes. These were 1086 C>A V308V, 1638 G>A S546S, and 1986 C>T Y642Y in KCNQ1 and 84 G>A S29S, 112 G>A S38G, and 253 G>A D85N in KCNE1. No base changes were identified in KCNE2.

### Discussion

In this study we produced a robust and reproducible set of primers for PCR/SSCP analysis of all five genes involved in the long QT syndrome. We also defined the exact PCR conditions for a successful amplification of every PCR fragment, which allows effective mutational analysis of the five known LQT genes. In particular, for KCNQ1 and HERG we based our analysis on primers published in two previous studies, Splawski et al.19 and Itoh et al.,23 respectively. However, PCR conditions for a number of fragments had to be optimised, as in our experience some PCR products amplified poorly under the original conditions. In addition, new primers were needed for KCNQ1 exons 9, 13, and 15. Based on the details given in table 1, all KCNQ1 exons can now be amplified without the use of formamide. Using our PCR methods, mutation screening of HERG can be achieved by amplifying only 19 fragments compared to 2017 and 24.28 This was made possible by recombining existing primers in a more effective way and then optimising PCR conditions for each fragment. For example, HERG exon 6 can be amplified in two fragments instead of three as used by Itoh et al.23 and there is no need for nested primers for exons 1 and 11 of the same gene.19

Genomic organisation and sequence of the SCN5A gene were first reported by Wang et al.24 In that study a total of 41 primer pairs were used to determine the sequence of 28 exons by direct sequencing. Several studies have since used those primers for mutational analysis of some SCN5A exons by SSCP.25–27 However, a number of PCR fragments are too large for effective SSCP analysis and contain long intronic sequences of unknown composition. Using the original set of primers, we sequenced all SCN5A exons and then produced several new PCR fragments suitable for SSCP analysis. For amplifying KCNE1 and KCNE2 fragments, no changes were made to the published PCR methods as they were found to work well. However, we recombined the existing primers in a way that permits amplification of the entire coding region of these genes in two fragments instead of the three used in previous studies.16 19

PCR products were analysed on SSCP gels by combining more than one fragment in each lane. In that way a large number of fragments can be screened on the same gel in various combinations depending on their electrophoretic mobility, thus reducing the number of gels needed for mutational screening. Evaluation of our system using DNA samples from sudden death cases and controls detected four known polymorphisms and two novel changes in SCN5A and KCNE1. In the first gene we found two SNPs at amino acid positions 546 and 64228 and a novel one at position 308. On the other hand, in KCNE1 we report a novel SNP (84 G>A S29S) and two known polymorphisms at positions 38 and 85.29 30 Owing to the nature of these two novel changes, we speculate that they may be benign polymorphisms even though they were not observed in 40 controls analysed. These findings provide good evidence that the methods described in this study, considering their limitations, can be effective for screening the known LQT genes for mutations.

Tripllication of several PAR1 genes and part of the *Homo sapiens* specific Yp11.2/Xq21.3 region of homology in a 46,X,t(X;Y)(p22.33;p11.2) male with schizophrenia

Norman L J Ross, Jian Yang, Carole A Sargent, Catherine A Boucher, Shinichiro Nanko, Rekha Wadekar, Nic A Williams, Nabeel A Affara, Timothy J Crow
In the absence of consistent linkage, one approach to finding genes associated with psychosis is through analysis of cytogenetic anomalies. One such anomaly is the case of an XX male with schizophrenia. In general, XX maleness is the result of the transfer of the testis determining factor (SRY) to the X chromosome as a result of an abnormal X-Y interchange involving the non-recombining region of Yp and homologous sequences in Xp. We showed previously that the breakpoint on the Y in this case is within the distal Yp11.2/Xq21.3 region of homology.

In this study we have characterised the Y breakpoint using a sequencing approach and fluorescence in situ hybridisation (FISH). We have shown that the abnormal X-Y interchange occurred between retroviral long terminal repeats (LTR). This is distinct from previously described translocations, which frequently involve hot spots such as the protein kinase gene (PRK) that has homologues on both Yp and Xp.

Cloning of the Yp/Xp junction fragment allowed the development of an X specific STS for radiation hybrid mapping, which places the X chromosome breakpoint within the PAR1. The breakpoint on the X chromosome is unusual in this category of XX male patients, as most occur proximal to the pseudoautosomal boundary (PARX). Only one breakpoint within PAR1 has previously been reported, and in this patient the translocation is mediated through an Alu-Alu recombination and the Y breakpoint is also within the Yp11.2 region of homology with Xq21.3, but is located telomeric to that in the present case. Unfortunately, no details of the psychiatric phenotype in that case are available (D C Page, personal communication).

Materials and methods

PATIENT

The XX male patient investigated in this study is Japanese and has been described previously. There was no family history of mental illness. He married but has no children. He was admitted to hospital with a diagnosis of schizophrenia but showed little response to neuroleptic medication. After a second admission, he remained in hospital for 30 years with chronic delusions. He was of dull normal intelligence (full scale WAIS 72, performance IQ 68, verbal IQ 55) with blunted affect. His symptoms satisfy the DSM-III-R criteria for the diagnosis of schizophrenia. Cytogenetic studies showed a 46,XX karyotype. No family history of psychosis was noted and no material was available from other family members.

CELL LINE

Lymphocytes from the patient transformed with Epstein Barr virus (EBV) were the source of genomic DNA and of metaphase chromosomes. The transformed cells were cultured in RPMI640 medium supplemented with 10% fetal calf serum (FCS).

EXTRACTION OF GENOMIC DNA

DNA was extracted from transformed lymphocytes using Genomix kits (Talent/VH Bio, Newcastle Upon Tyne, UK) according to the manufacturer’s instructions. DNA obtained from the blood of normal Japanese males and females served as controls.

PCR AMPLIFICATION OF SEQUENCE TAGGED SITES (STS)

Twenty µl reactions containing 100 ng of genomic DNA, 12 pmol of each primer, 0.2 mmol/l of each dNTP, 0.4 U of Taq polymerase (Promega Inc), and 1 x PCR buffer (Promega Inc) were amplified using a thermocycler (Genetic Research Instrument) as follows. After an initial denaturation step at 94°C for five minutes, samples were subjected to 35 cycles for 30 seconds at 94°C, 30 seconds at 55°C, one minute at 72°C, followed by a final step for 10 minutes at 72°C. The annealing temperature varied depending on the Tm of the primers. Products were analysed by electrophoresis on 1-2% agarose gels.

DNA SEQUENCING

PCR amplification of STSs were scaled up two to threefold and the products were purified using Qiaquick PCR purification kits (Qiagen Ltd, UK). The purified products were sequenced using dye terminator cycle sequencing (Big Dye sequencing system, Applied Biosystems Inc) and were analysed by an ABI 373 sequencer (Applied Biosystems Inc). Sequencing of the cloned 3 kb Yp/Xp junction fragment was carried out in a stepwise manner by primer extension initiated from both T7 and Sp6 ends of the cloning vector.

BAC AND PAC CLONES

BAC clones derived from the Yp region homologous to Xq21.3 were gifts from Dr Gareth Howell (Sanger Centre). PAC clones were isolated from the RPCI-1 library (available through the HGMP resource centre, Hinxton) by screening with X/Y homologous STS primer pairs.

Transformed bacteria were cultured in L-broth containing chloramphenicol or kanamycin as appropriate and DNA was extracted using an alkaline lysis method. Clones were tested for the presence of STSs to confirm that they were authentic. DNA from clones selected for in situ hybridisation were purified using Qiagen Midi columns (Qiagen Ltd, UK).

PCR PRIMERS

Primers for amplification of STSs have been described previously. Other primers were as follows: J: 5’ CAGCAACATGTATTGAGAAATACTAC; M: 5’ TGTGGTGCTGTCGCTGCTGCT; N: 5’ ACGTACATTGCGTGAAGGCCA; O: 5’ ATAC; P: 5’ TCTGCTGCCTGCCTGAAGGCCA; Q: 5’ CAGTACATTGCGTGAAGGCCA; R: 5’ ACGTACATTGCGTGAAGGCCA; S: 5’ TGTGGTGCTGTCGCTGCTGCT; T: 5’ ACGTACATTGCGTGAAGGCCA; U: 5’ TGTGGTGCTGTCGCTGCTGCT; V: 5’ ACGTACATTGCGTGAAGGCCA; W: 5’ TGTGGTGCTGTCGCTGCTGCT.

Primers J and M are Y specific at their 3’ ends. They were designed by comparing the sequence of the relevant part of Yp (from PAC clone dJ145K17 and GenBank entry AC012077) with the Xq21.3 homologous sequence (AL121823 from the Sanger Centre). Primers N, O, and P were used to amplify the relevant part of the X chromosome.
were designed from the Yp sequence. Forward (F) and reverse (R) primers for amplifying the fragment spanning the Tsp509I restriction enzyme sites in Yp were 5’CTCTGCTTCTCATC
CCCAATGAA and 5’ GTGATTGGGFAAAGTGGCT, respectively.

INVERSE PCR
Five µg amounts of genomic DNA from the XX male, a normal Japanese male, and a normal Japanese female were digested to completion with BamHI at 37°C overnight. The digested DNA was extracted with phenol/chloroform, chloroform, precipitated with ethanol in the presence of 0.3 mol/l sodium acetate, and resuspended in water. A total of 200 ng of digested DNA were self-ligated overnight at 4°C in a 40 µl reaction containing 1 µl ligase buffer (Promega) and 0.15 U T4 ligase (Gibco). Ligated preparations were denatured at 94°C for five minutes and quenched on ice before use in PCR reactions. Approximately 20 ng of ligated DNA were the templates for the first round of inverse PCR using the Extensor High Fidelity PCR kit (Advanced Biotechnologies), according to the manufacturer’s instructions. Fifty µl reactions containing 1 × buffer 1, 350 µmol/l of each dNTP, 1.75 mmol/l MgCl2, and 2 U of Taq polymerase were subjected to 35 cycles of amplification. Cycling parameters were as follows: an initial denaturation step at 94°C for two minutes, followed by 35 cycles of 94°C for 15 seconds, 66°C for 30 seconds, 68°C for five minutes, and a final extension step at 72°C for five minutes.

Primers J and P were used for the first round of inverse PCR and a secondary PCR was carried out with primers J and O essentially as above using 1/10 dilution of the first PCR reaction products as template.

CLONING OF THE Yp/Xp JUNCTION FRAGMENT
Inverse PCR products were cloned using the pGEM TA cloning kit (Promega) according to the manufacturer’s instructions.

FLUORESCENCE IN SITU HYBRIDISATION (FISH)
BAC and PAC clones containing relevant STS markers were selected for FISH analysis. Total BAC and PAC DNA was labelled with biotin by nick translation (Biotin-nick translation kit, Boehringer Mannheim). Metaphase chromosomes from the patient and normal controls were hybridised to biotin labelled DNA and bound DNA was shown using fluorescently labelled antibiotin antibody according to standard protocols.

ANALYSIS OF MICROSATELLITE MARKERS
To refine the breakpoint in Xp22.3, the number of alleles of a variety of microsatellite markers mapping in Xp22.3 was estimated in the XX male and normal Japanese male and female DNA. Genomic DNA was amplified through PCR using the relevant primers as described in the Genbank and Genethon databases. One of each pair of primers was labelled with cy5 and the PCR products were analysed in a denaturing polyacrylamide sequencing gel using the Alf Express sequencer (Pharmacia).

RADIATION HYBRID MAPPING
The STS BPX, developed from the X specific microsatellite region of the breakpoint junction fragment (primers AP and AR), was mapped using the Genebridge 4 radiation hybrid panel (HGMP Resource Centre, Hinxton). The pattern of positive and negative hybrids was converted to a data vector and submitted to http://www.sanger.ac.uk/Software/RHserver/RHserver.shtml for two point RHMAP analysis with framework markers. The Genemap99 at the Genbank web page http://www.ncbi.nlm.nih.gov/genemap99/map.cgi?CHR=X was consulted to identify the map location of these markers. Vectors for the highest scoring framework markers and their neighbours were retrieved from EBI at http://corba.ebi.ac.uk/RHdb/species/HUMAN/gm98.html and reanalysed with the BPX vector to position BPX within the radiation hybrid map.

RESULTS
MAPPING THE BREAKPOINT ON THE Y CHROMOSOME
Since previous studies had indicated that the breakpoint mapped in the region of Yp11.2 homologous to Xq21.3 (fig 1), further mapping of its location required an approach that could discriminate between homologous sequences derived from X and Y chromosomes. Initial PCR analysis confirmed that the SRY marker was present in the XX male, the marker DXY5156 showed the Y specific polymorphism, and the Y specific STSs sY58 and sY78 which map outside the X-Y homology region were not present (not shown). Further experiments involved sequencing STSs in the genomes of the XX male patient and normal Japanese males and females. The method depends on the capacity to detect heterozygosity and assumes that the PCR conditions can amplify both X and Y derived STSs efficiently. In the case of GMGX6, Y specific primers gave amplification with only the normal male and the XX male (not shown).

The results of analysis of 22 STSs within the X-Y homology region are summarised in table 1 and fig 1. A number of cases were uninformative because there were no differences between males and females. The most proximal Y marker present was GMGX6Y, and the first confirmed deleted marker was the Y homologue of 13d. The distance between GMGX6Y and 13d is approximately 500 kb. To localise the breakpoint within this region further, PAC and BAC clones selected for the intervening non-informative STSs were used in FISH.

FLUORESCENCE IN SITU HYBRIDISATION (FISH)
The results of in situ hybridisation obtained with the XX male chromosomes are shown in fig 2. The BAC clone BA32K15 (fig 1) containing sY41 and sY42 hybridised to the Xq region of both X chromosomes (arrows 1 and 2 in fig 2A) but also to a second site at the telomeric end of the abnormal X chromosome (arrow 1). Similar results were obtained using the PAC clone dJ145K17, which spans the sY42, 13d, and 2450L markers. However, in
this case, the signal in the abnormal Xp (arrow 1, fig 2B) was fainter than in Xq indicating that only part of this sequence was present on the telomere of the abnormal X chromosome. Finally, the BAC clone BA240N18, which is centromeric to 13d and contains STS 2450L, hybridised to Xq of both chromosomes but not to Xp (fig 2C). These results, together with the STS analysis discussed above, confirm that the breakpoint on Yp lies between the markers sY42 and 13d.

**Figure 1**

(A) Schematic illustration (not to scale) of X and Y chromosomes showing the regions involved in the transposition. The 3.5 Mb Xq21.3/Yp11.2 region of homology comprising STS markers sY20 to GXY5 is indicated (black box). Grey box represents the pseudoautosomal region (PAR1) of X and Y. Dark grey box indicates the male specific gene SRY. (B) Map of Yp showing selected STS markers within the 3.5 Mb region homologous to Xq21.3. Arrow indicates the location of the breakpoint (Bkpt) between 13d and sY42 markers in the abnormal paternal X chromosome of the XX male with psychosis. GMGXY4, GMGXY5, GMGXY6, GMGXY9, and GMGXY12 have been abbreviated. (C) Enlargement of part of Yp11.2 showing the location of BAC and PAC clones used for FISH.
mapped within the region defined by the X specific Tsp509I RE site and primer M.

THE JUNCTION FRAGMENT

Inverse PCR and cloning of the Yp-Xp junction fragment

To isolate the junction between Yp and Xp, nested inverse PCR was performed. Genomic DNA was digested with BamHI, religated at low concentration, and used as template for inverse PCR. Primer locations are indicated in fig 3. Primers J (designed to be Y specific at its 3’ end) and primer P were used for the first round of PCR and primers J and O for the secondary PCR. The results of the secondary PCR with primers J and O are shown in fig 4C. A major unique fragment (approximately 3 kb) was obtained from the XX male DNA but not from normal Japanese male and female DNA. This fragment was gel purified and cloned. Ten recombinant clones with an insert of expected size were sequenced from both ends. Three clones contained the expected ends as shown by the presence of primers J and O in the sequence and a BamHI site at the expected distance from primer O.

The complete sequence of the junction fragment from one of the clones (clone 10) is shown in fig 5. The sequence 3’ of the J primer contains nucleotides (position 23-339 inclusive) present in Yp11.2 but not in Xq21.3, that is, the sequence is 100% Y derived. From position 551 onward, there are a number of single or double nucleotides which are neither Xq21.3 nor Yp11.2 derived. We believe that this indicates the presence of Xp derived sequences. Consequently, the breakpoint on the Y chromosome has occurred within the region 340-550 bp. This is consistent with and extends our independent data (fig 4A) which indicated a difference in a RE site for Tsp509I in the XX male that also occurred in the Yp sequence, but not the sequence from Xq21.3.

Thus, fig 5 shows the sequence GATT at position 223 in the XX male, also found in Yp11.2, whereas the Xq21.3 derived sequence has the Tsp509I RE site AATT at this point. This is also consistent with results shown in fig 4B which showed the absence of Y specific sequence at the primer M site in the XX male. Thus, at position 665, the XX male sequence has a G instead of A at the 3’ end of the primer and a C instead of G at the fourth nucleotide from its 5’ end. Primer O is at the expected distance from the BamHI site (deduced from the sequence of Yp).

To confirm that the cloned fragment indeed spanned the Yp-Xp junction, a PCR was carried out using primer J and primer AC which is located within the putative Xp region. Fig 4D1 shows that a product of expected size (800 bp) was amplified using the XX male genomic DNA as template but not normal Japanese male and female DNA controls. The results show that the fragment is a unique sequence present only in the XX male. A second set of primers confirmed this result (not shown). A control for the DNA template amplification is shown in fig 4D2.

Analysis of the sequence of the junction fragment

Most of the 2975 bp sequence consists of LTR and LINE repeats. Clearly these must have been involved in the abnormal recombination between Yp and Xp during meiosis, forming the abnormal paternal X of the XX male.

---

**Figure 3** (A) Sketch of part of Yp showing the location of primers and the relevant restriction enzyme Tsp509I (Tsp) sites (not to scale). (B) Sketch of the Yp:Xp junction showing the location of the breakpoint, relevant Tsp509I (Tsp) sites, and primers J and AC which were used to amplify a unique fragment in the XX male. Note presence of two Tsp509I RE sites 184 bp apart in Yp within the sequence flanked by F and R primers.
Since these repeats share extensive sequence identity, it is difficult to map the breakpoint exactly. However, it was possible to identify LTR sequences which contained nucleotides present in Yp but not Xq21.3 and nucleotides that were neither Yp nor Xq21.3 derived. Part of the sequence (which did not consist entirely of repeat elements) contained 14 CpG dinucleotides in a 270 bp region which showed 97% identity with a CpG island sequence (Genbank Accession Z57539). This is of interest since it suggests that there could be genes in Xp downstream of the breakpoint that might be affected by the Yp translocation.

To date we have not found convincing identity between the sequence 3’ of the breakpoint and sequences in Xp as a whole or Xp22.3 in particular. However, sequencing of this region by the Human Genome Project is not yet complete. Database searches for identity are further complicated because of the presence of LTR repeat sequences in many chromosomes.

**MAPPING THE BREAKPOINT ON THE X CHROMOSOME**

**Microsatellite markers**

In an attempt to map the breakpoint on Xp22.3, we analysed the number of alleles for microsatellite markers in the genome of the patient. The results showed that the patient has two alleles for DXS6807 indicating that the breakpoint is distal to this marker. Analysis of markers DXS1233, DXS7100, DXS1060, DXS987, and the PAR1 markers DXYS228 and DXYS233 were uninformative. Fig 6 shows the chromosome rearrangement and the

![Figure 4](image-url)

*Figure 4* (A) Results of Tsp509I digestion of PCR product obtained with primers F and R (see fig 3) showing that the XX male patient has a male genotype at this point. (B) Results of a PCR with primers M and N (see fig 3) showing amplification of the expected size product (124 bp) from a normal Japanese male but not from a normal Japanese female or the XX male. Since primer M is Y specific at its 3’ end, the results indicate that the XX male does not have Yp derived sequence at this point. (C) Results of a PCR with primers J and O (see fig 3) showing amplification of a unique major 3 kb band in the XX male. This is the secondary PCR subsequent to inverse PCR with primers J and P (D1). Results of a PCR showing that primers J and AC amplify a fragment of expected size (800 bp) in the XX male but not in normal Japanese males and females. This confirms that the fragment is unique and spans the Yp/Xp junction in the XX male. (D2) Results of a PCR using sY46 primers as a control confirmed that all three genomic DNAs could be amplified and generated the expected 200 bp product.

scribed structural abnormalities of Xp22.3.

tive to markers, genes, and previously described structural abnormalities of Xp22.3.

Figure 5  Multiple alignment of part of the sequence of the 3 kb Yp/Xp junction fragment and homologous sequences in Xq21.3 and Yp sequences from position 551. We expect the sequences from position 551 onwards to be Xp22.3.

position of the breakpoints in this patient relative to markers, genes, and previously described structural abnormalities of Xp22.3.

Radiation hybrid mapping

The STS BPX was used to amplify the GeneBridge 4 radiation hybrid panel. The expected

www.jmedgenet.com
product size (862 bp) was amplified from the human control DNA but not from the mouse and hamster DNA. The positive and negative results of the hybrid amplifications were converted to a vector and submitted to the Sanger Centre web site for two point RHMAP analysis. Lod scores of 20.9 and 16.5 were obtained for the framework markers AFMa284xc9 and AFMb290xg5, respectively. Based on the Genebridge 4 radiation hybrid map, Genemap99, both framework markers are located in PAR1 with AFMa284xc9 being more distal. The Genebridge 4 vectors for these framework markers and their neighbouring markers (stSG28551, stsf04211, stSG38742, stSG3076, stSG15779, stSG25747, stSG21520) were extracted from the EBI database. Analysis of these vectors positioned BPX between AFMa284xc9 (DXYS233) and AFMb290xg5 (DXYS228), with an identical vector to the markers stSG28551 and stsf04211 acetylserotonin N-methyltransferase-like (ASMTL) but distal to acetylserotonin N-methyltransferase (ASMT) (fig 6).

Discussion

The paternal X of our patient was the result of abnormal recombination between Xp and Yp during male meiosis in an extensive region of retroviral LTR repeats. These particular repeats are in low abundance in the genome and at least 95% identical between loci on Xp and Yp. Approximately 4 Mb of Yp, including SRY, were translocated to Xp22.33 on the abnormal X chromosome. Single/double nucleotide differences between the X and Y in the region of X-Y homology were exploited to determine the origin of STS markers in the XX male by sequencing and restriction enzyme analysis. These differences also allowed the design of primers for Y specific PCR and inverse PCR, leading to the cloning and sequencing of the translocation junction fragment. We were thus able to map the breakpoint on Yp to within a 210 bp interval (between sY42 and 13d) and develop a new STS (BPX) from the putative Xp22.33 derived sequence. The Yp breakpoint lies within 180 kb of repeats comprising various LTR and LINE elements, with no genes yet described within the immediate

Figure 6  Ideogram showing illegitimate recombination between Yp11.2 (black box) and Xp22.33 (grey box) during paternal meiosis resulting in an abnormal paternal X in the XX male patient. The breakpoint is between sY42 and 13d markers in Yp11.2 and distal to ASMT in Xp22.33. The region comprising the genes XG to ASMT and probably also ASMTL is duplicated in the abnormal paternal X and therefore triplicated in diploid cells of the patient. Grey box represents the pseudoautosomal regions (PAR1) of X and Y. Dark grey box indicates the male specific SRY gene. Black box indicates Yq21.3/Yp11.2 homology region. Unfilled box shows part of Xp22.3 proximal to PAR1. Relevant markers and genes are indicated. ASMT: acetylserotonin N-methyltransferase, ASMTL: acetylserotonin N-methyltransferase-like, STS: steroid sulphatase deficiency, SS: SHOX short stature gene, KAL: Kallmann syndrome gene. Other genes MIC2 and XG are indicated.

Letters

www.jmedgenet.com
vicinity. The Xp22.33 STS BPX was mapped to PAR1 between framework markers DXYS233 and DXYS228 using the Genebridge 4 radiation hybrid mapping panel. Fine mapping positioned BPX close to ASMTL and distal to ASMT.

This is the second patient to be characterised with a translocation between Yp sequences in the Xq21.3/Yp homology block and the Xp PAR1. In the case described previously, the Yp breakpoint was defined just telomeric to DXYS5 within the Xq21.3/Yp homology block, and the Xp breakpoint distal to DXYS28. Thus, this patient has a smaller contribution from Yp, but an additional 1 Mb from the X chromosome. Both cases are typic- al of (Y+) XX males, as they have triplication of PAR1 genes, and in this respect are similar to people with sex chromosome aneuploidies (XXX and XXY). In contrast to Klinefelter (XXY) syndrome, our patient, like other XX males, has stature within the normal female range. Triplication including PAR1 was also found in one subject bearing an isodicentric chromosome derived from Yp with mental retardation and in a male patient with a duplication of distal Xp with autism who also had severe mental retardation. In contrast, an atypical XXY subject has been described with a partial deletion of the short arm of one X chromo- somes without cognitive impairment. These cases are consistent with the hypothesis that triplication of genes in the proximal part of PAR1 (ASMT, MLC2R, MIC2, XG, possibly ASMTL, and any as yet unknown genes) increases the risk of cognitive impairment. However, the cognitive impair- ment in our patient is somewhat more severe than is generally seen in Klinefelter syndrome in which it is mild and selective to verbal abil- ity. The relationship of cognitive function to gene dosage of PAR1 therefore remains unclear.

An increased prevalence (two to threefold) of schizophrenia in Klinefelter syndrome (47, XXX), 47,XXX, and 47,XY Yp11.2/Xq21.3 homology block. The largest
class of Yp (Y+) XX males is the result of illegiti- mate recombination in hot spots involving the PRKX/PKRY genes. The breakpoints in these patients involve the transfer of material from the short arm of the Y chromosome including the Yp block of Xq21.3/Yp11.2 homology to the abnormal X chromosome. There is no evidence of an increased incidence of psychosis in such patients. Therefore, it is unlikely that additional copies of genes nor- mally found in the Xq21.3/Yp11.2 homology block contribute directly to a psychotic pheno- type. Although it is possible that triplication of proximal PAR1 gene(s) contributes to psychos- is in this patient, the fact that most subjects with supernumerary sex chromosomes do not suffer from psychosis reflects a more complex pathogenesis.

The chromosomal rearrangement in the XX male may affect gene dosage in a number of ways. First, increased gene dosage may lead to an abnormally high level of the triplicated gene products, for example, in PAR1 as noted. Sec- ond, the rearrangement may disrupt genes or affect expression through a position effect caused by the juxtapositioning of X and Y chromosome material. This could lead to either an up or downregulation of PAR1 or transferred Yp genes. Third, the rearrange- ment may alter any established imprint or X inactivation status of PAR1 or Yp genes. Investiga- tion of these possibilities in this patient may indicate which of the triplicated loci are most likely to be involved in the phenotype.

We are grateful to the UK Medical Research Council, the Stanley Foundation, SANE, and the Denise Callahan Research Fellowship for support and to Dr Mark Ross and Dr John Delisi (The Sanger Centre) for advice and for supplying PAC and BAC clones. We are also grateful to Drs B Gaudet, A Brown, and M H Shen (Biochemistry Department, Oxford University) for access to their facilities and advice on FISH and to the MRC-funded DNA sequencing facility in the Department of Biochemistry, Oxford University. We are grateful to Dr L E DeLisi for help in preserving the cell line. CAS and CAB wish to acknowledge the support of PIC (the Pig Improvement Company).

EDITOR—Corneal dermoids (CND) (MIM 304730) are rare, congenital, benign tumours involving the cornea. Histologically, the dermoids consist of a combination of ectodermal elements including keratinised epithelium, hair, and sebaceous glands and mesodermal elements including fibrous tissue, fat, and blood vessels in different proportions. The tumour is defined as a choristoma since it is histologically a normal tissue in an abnormal site. Clinically, these tumours appear as opacification of the cornea at birth and may result in blindness (fig 1). Treatment includes surgical removal of the tumour with corneal transplantation. When the tumours affect both eyes, surgical intervention is indicated within the first 3 months of life since untreated cases may be irreversible by that time.

Most CND cases are sporadic and unilateral. However, three hereditary forms associated with congenital dermoids involving the cornea have been described. The Goldenhar syndrome (oculoauriculovertebral dysplasia, MIM 164210) is a multiple anomaly syndrome that involves the eyes, ears, and the vertebral column. The dermoids are mostly unilateral, originating in the periphery of the cornea at the limbus. Although most cases are sporadic, familial cases with an autosomal dominant mode of inheritance have been reported. The second form with hereditary dermoids of the cornea is found in a male: further delineation of a possible sex influencing region on the X chromosome. Figure 1 Corneal dermoids as seen immediately after birth in subject IV.8.
Xp22.2. Here, we report the analysis of the extended family to establish linkage.

Case reports
Twenty three members of a four generation family were ascertained in our centre. Clinical data from the 15 subjects who participated in the previous linkage study were available to us but blood samples were available for only 10 out of the 15. II.2 and II.10 declined participation in the current study. In addition, we studied seven family members, including three affected males, not previously described (IV.2, IV.3, IV.5-IV.9). This study was approved by the Albert Einstein College of Medicine Institutional Review Board, in accordance with the guidelines of the Office for the Protection from Research Risks, and informed consent was obtained before participation (CCI 91-157).

All family members including carriers and unaffected members underwent full ophthalmic examination in our centre and ophthalmic records and histopathology slides of affected males were reviewed. We identified six males out of 23 family members who were affected with congenital corneal dermoids. The 17 unaffected family members did not exhibit any medical or ophthalmic condition that could be attributed to or associated with CND. The pattern of transmission is consistent with an X linked recessive mode of inheritance as indicated by the presence of only affected men, an absence of male to male transmission, and unaffected obligate carrier females (fig 2). In all cases the dermoids appeared as a bilateral, superficial, greyish layer with irregular, raised, whitish plaques and fine blood vessels that covered the centre of the cornea. The peripheral border of the cornea was intact in all cases. The ophthalmic examination of affected males was consistent with the previously described examination of subjects III.8, III.9, and IV.1.4 Briefly, ocular examinations showed normal adnexal structures, eyes were orthophoric to Hirschberg testing, and eye movements were conjugate and normal. Schiotz tonometry

Figure 2 Haplotype analysis of the four generation family segregating X linked CD. The at risk haplotype is blackened to show recombinations. Carrier females are indicated by a black dot within a circle and affected males are indicated by blackened squares. Unblackened squares and circles without a black dot denote unaffected males and females not known to be carriers, respectively. Asterisks show subjects who were analysed in the previous report but for whom blood samples were not available for current linkage analysis.

6.2 and 5.6 kb on a genomic Southern blot and a probe which detects two reported Xp22.2 locus with the DXS43pD2 type analysis. We initially studied the previously endothelium, were intact in all cases. The inner layers, Descemet’s membrane and the cases and Bowman’s membrane was absent in epithelium was found to be keratinised in three. The outer layer of stratified squamous two cases and sebaceous glands were present in hair follicles and hair shafts were present in irregular collagenous connective tissue in all cases with sparing of the corneal periphery. Hair follicles and hair shafts were present in two cases and sebaceous glands were present in three. The outer layer of stratified squamous epithelium was found to be keratinised in three cases and Bowman’s membrane was absent in these cases and in one additional case. The two inner layers, Descemet’s membrane and the endothelium, were intact in all cases.

A total of 17 subjects were subjected to genotype analysis. We initially studied the previously reported Xp22.2 locus with the DXS43pD2 probe which detects two PvuII alleles of sizes 6.2 and 5.6 kb on a genomic Southern blot and with nine additional microsatellite markers flanking DXS43pD2 at Xp22.1-p22.3. Briefly, polymorphic markers and genetic distances were obtained from the Centre for Medical Genetics, Marshfield and the Genome Database (http://www.jmedgenet.com). For genotyping, the reverse primers were radiolabelled with [32P]-ATP, and the PCR product was amplified under standard reaction conditions. The PCR product was denatured by adding 20 µl of stop solution containing 5 M phosphoric acid to the reaction mixture and heating for 10 minutes at 65°C. The radiolabelled PCR products were separated on 6% acrylamide denaturing sequencing gels, and alleles were assigned according to their molecular weight.

Linkage analysis was performed assuming an X linked recessive mode of inheritance with complete penetrance and without phenocopies. The frequency of the disease predisposing allele was set to 0.0001. Marker allele frequencies were estimated from the founders. Disease marker pairwise linkage analysis was performed using MLINK from LINKAGE v 5.2.11 because of the opacification, but intraoperatively were described as normal and clear. The anterior chambers and fundi could not be seen because of the opacification, but intraoperatively were described as normal and clear. The anterior chambers and fundi could not be seen because of the opacification, but intraoperatively were described as normal and clear. The anterior chambers and fundi could not be seen because of the opacification, but intraoperatively were described as normal and clear. The anterior chambers and fundi could not be seen because of the opacification, but intraoperatively were described as normal and clear.

In conclusion, we mapped the gene for CND to chromosome Xq24–qter, within a 45 cM region, by using haplotype and linkage analyses. Although CND was mapped to a large interval with six markers with lod scores of more than 2.8 at θ=0.00, our findings re-emphasise the caution that is required in interpreting linkage results in a single family. The
addition of new members to this family and their inclusion in the study showed two new recombinations in a locus previously suggested to be linked to the disorder.

The unique features of the corneal dermoids in this family were the bilaterality of the tumours and their localisation in the central matrix of the cornea while sparing the periphery of the cornea, Descemet's membrane, and the endothelial membrane. Since corneal dermoids are considered to be an aberrant development of ectopic tissue in the cornea, it can be speculated that it results from a mutation in a gene that has a role in the normal differentiation of the matrix component of the cornea. The interval found to be linked to CND is currently known to contain 119 genes of which 38 have protein products with unknown function or an abnormal function which has not been implicated in any known disorder. Examination of the known data regarding these genes failed to pinpoint any target gene that may have a role in corneal development. Since there are no additional informative recombinations in this interval, the candidate region cannot be further narrowed and only additional families with XLCD can assist in advancing mapping and identification of the XLCD gene.

- A four generation family with congenital corneal dermoids segregating as an X linked trait was studied.
- Of 23 family members, bilateral and central dermoid tumours of the cornea were identified at birth in six males.
- Linkage analysis performed for 17 subjects localised the gene for the disease to a 45 cM interval distal to DXS1001.

Satellites on the terminal short arm of chromosome 12 (12ps), inherited through several generations in three families: a new variant without phenotypic effect

Lionel Willatt, Andrew J Green, Dorothy Trump

Editor—Five of the human autosomes are acrocentric, chromosomes 13, 14, 15, 21, and 22, and are identified by the presence of satellite short arms. These short arms contain three bands, p11, p12, and p13, and are composed of repetitive DNA containing satellite repeats and copies of ribosomal RNA genes. Band p11, the pericentricromeric region, is composed of several types of tandemly repeated DNA including satellites I, II, III, and IV, and beta satellite DNA. Band p12, the satellite stalks, contains multiple copies of genes coding for ribosomal RNA and is known as the nucleolar organiser region (NOR) as the nucleolus is formed by an aggregation of ribosomal RNA. This can be recognised by staining with silver nitrate (AgNOR staining). Band p13 contains beta satellite DNA and terminal telomeric sequences.

Loss or gain of the short arm of acrocentric chromosomes occurs without apparent phenotypic effect. For example, Robertsonian translocations occur when two acrocentric chromosomes are joined by centric fusion with the resulting loss of the short arm material and have no associated phenotype in this euchromatically balanced form. Chromosomal rearrangements involving the short arms of acrocentric chromosomes are a well known form of chromosomal variation. The most common variation results from rearrangements between the short arms of acrocentric chromosomes. Thus, the satellites of acrocentric chromosomes range in size from no satellites to double or treble satellites as shown by AgNOR staining. Translocations between the short arm of an acrocentric chromosome and the heterochromatic region of the long arm of the Y chromosome, resulting in acrocentric chromosomes with Y chromosome heterochromatin in place of satellites and satellited Y chromosomes, are also observed. More rarely, non-acrocentric chromosomes with terminal satellites have been described which arise from a translocation between the short arm of an acrocentric and the terminal region of another chromosome. Interstitial insertion of NORs from an acrocentric chromosome into another chromosome, giving rise to non-acrocentric chromosomes with interstitial satellites, is a rare form of chromosomal rearrangement without phenotypic effect. In contrast to these variant chromosomes, satellited non-acrocentric chromosomes resulting from an insertion or translocation between an acrocentric chromosome and another chromosome, in which there is loss of material from the non-acrocentric chromosome, are associated with an abnormal phenotype.

When a satellited non-acrocentric chromosome is observed it is essential to distinguish between these two possibilities.

We describe three pedigrees in which multiple family members have NORs at the telomeric region of the short arm of one chromosome 12 (12ps).

Case reports

In family 1, parental chromosome studies were undertaken following a stillbirth at 38 weeks. These studies showed a chromosome 12 with positively NOR staining satellite stalks at the end of the short arm (12ps) in the mother, who had an otherwise normal female chromosome complement. The paternal karyotype was normal. Family studies showed that this satellited chromosome had been inherited from her mother. Each of these women was well with no associated phenotype. There was no other significant family history (fig 1).

In family 2, chromosome analysis of an amniotic fluid sample received for maternal age showed a male karyotype with positively NOR staining satellite stalks at the end of the short arm of one chromosome 12 (12ps). Parental chromosome analysis showed that the 12ps chromosome was paternal in origin with no associated phenotype. The family history was unremarkable. The pregnancy proceeded to term and the child at the age of 3 years has no developmental problems (fig 1).

In family 3, a chromosome 22 (tuple 1) microdeletion was identified in a 3 month old child with tetralogy of Fallot and dysmorphic facies, consistent with DiGeorge/VCF syndrome. Parental chromosome studies showed that this microdeletion was de novo. However, the father was found to have one chromosome 12 with positively NOR staining satellite stalks at the end of the short arm (12ps) with no
associated phenotype. The 12ps chromosome was not present in the index case (fig 1).

In a fourth family, a 13 year old girl was referred with short stature. Blood chromosome analysis showed the presence of positively NOR staining satellite stalks at the end of the short arm of one chromosome 12 (12ps). The remainder of the karyotype was normal and there was no evidence of mosaicism for 45,X in 30 cells examined. Parental karyotyping indicated that the chromosome 12 with positively NOR staining satellite stalks was maternally derived. The mother was of normal height and there was no family history of short stature. This family was subsequently identified as part of family 3 (fig 1).

Chromosome studies including GTL banding, silver staining (AgNOR), and fluorescence in situ hybridisation (FISH) studies were performed by standard techniques.6

Results

GTL banding showed no detectable loss of material from the satellited chromosome 12 in any of the families, with band p13 still present (fig 2, left). Silver (AgNOR) staining confirmed the presence of NOR positive material (fig 2, middle). The NOR bearing satellited chromosome took part in NOR associations with acrocentric chromosomes. The alpha satellite (centromeric) probes for the acrocentric chromosomes 13/21 (D13Z1), 14/22, and 15 did not hybridise to the satellited chromosome 12, thus confirming it was monocentric. FISH studies with the chromosome 12 short arm...
subtelomeric probe VIJ\textsuperscript{22} showed no detectable loss of material from the 12ps chromosome (fig 2, right).

**Discussion**

We have described three families in which a satellited chromosome 12 (12ps) is inherited. There was no evidence for loss or gain of genetically significant material. The clinical indication for chromosome analysis of the proband was different in each case and both maternal and paternal transmission of the satellited chromosome was evident. In view of the lack of a consistent phenotype in the probands and the normal phenotype in the heterozygous parents, this satellited chromosome 12 appears to be a previously undescribed heritable variant chromosome, without phenotypic effect. Our detection of this rare variant in these three families makes it probable that they are related, especially as they all share a travelling, semi-nomadic lifestyle.

It is notable that the majority of reported cases of familial satellited nonacrocentric autosomes have been identified at prenatal diagnosis for maternal age, as was the case for family 2 in the present study.\textsuperscript{18} When a satellited nonacrocentric chromosome is identified at prenatal diagnosis, it is essential to distinguish between significant loss or gain of material and variant chromosomes. In some cases, satellited nonacrocentric chromosomes identified at prenatal diagnosis have been shown to be unbalanced products of a parental balanced translocation\textsuperscript{22-26} and the satellited chromosome in the proband has been associated with an abnormal phenotype. Gene density is high in the subtelomeric regions of chromosomes so particular care has to be taken before deciding that the integrity of this region has been maintained. In particular, cases of Wolf-Hirschhorn and cri du chat syndromes involving a satellited short arm of chromosomes 4 or 5 respectively have been frequently reported.\textsuperscript{27-29} In the family with a satellited 4 (qs) variant, described by Babu et al,\textsuperscript{30} the index case had an interstitial deletion of chromosome 4 in the region adjacent to the satellites (q35), thus explaining his developmental problems. Careful conventional banding analysis, exclusion of loss of subtelomeric regions by using commercially available subtelomeric FISH probes, and the demonstration of inheritance of the identical rearrangement from a phenotypically normal parent should provide reassurance.

In the family described by Mihelick et al.,\textsuperscript{18} the proband had craniorachischisis whereas other family members who carried the satellited chromosome 4 (qs) had a normal phenotype. This family was studied before the advent of FISH and it is probable that the craniorachischisis was a coincidental finding. The satellited chromosome 10 (qs) described by Storto et al.\textsuperscript{31} was unusual in being present in mosaic form in the father. This chromosome 10 with satellites must presumably have occurred for the first time in the father. Interestingly, as far as we are aware, there are no other published reports of de novo satellited nonacrocentric variant chromosomes. The lack of a clinical phenotype, and the normal hybridisation analysis with the chromosome 12p satellited probe would indicate that there has been no loss of the subtelomeric region of 12p in these families. However, it is impossible to exclude the possibility that this rearrangement is an interstitial insertion of a NOR into the most subtelomeric part of 12p, rather than a terminal attachment to 12p. The satellited chromosome 12 reported in the present study is different from the familial dicentric satellited chromosome 12 variant described by Watt et al.\textsuperscript{32} In their family, satellite material and a centromere from an acrocentric chromosome had been interstitially inserted into the proximal short arm of chromosome 12.

The case described by Miller et al.\textsuperscript{33} was unusual in that the satellited chromosome 4 (qs) did not stain with AgNOR staining in the proband, but was NOR positive in other family members including the father of the fetus. As judged by silver (AgNOR) staining, not all NORs are active in every cell. Of the 10 NORs present on the acrocentric chromosomes, most people have between four and seven that are active per cell.\textsuperscript{34} The satellited 4 (qs) in the proband appeared morphologically the same as in the other family members. It is possible that examination of more cells in the proband would have shown NOR staining in some cells. The possibility that the satellited chromosome 4 (qs) in the proband had lost its NOR activity cannot be excluded.

When a chromosome anomaly appears to be an apparently harmless variant, then there may be a dilemma regarding further family follow up. Taking blood samples for chromosome analysis may raise anxiety in the family needlessly and might also be a time consuming exercise. This has to be balanced against the problems associated with the unexpected finding of a satellited chromosome at prenatal diagnosis.

The satellites on acrocentric chromosomes show a considerable variation in size in the population. This is considered to arise from unequal recombination between acrocentric short arms at meiosis occurring in these regions of sequence homology. The close proximity of the repetitive sequences of the acrocentric chromosomes in a common nucleolus is also likely to favour recombination, even in mitosis.\textsuperscript{35} It is likely, for example, that the case of mosaic satellited chromosome 10 (qs) described by Storto et al.\textsuperscript{31} arose mitotically. Rearrangements resulting in nonacrocentric chromosomes may also arise because of sequence homology at the breakpoints and scattered within the genome are repeat sequences with homology to the acrocentric repetitive DNA.\textsuperscript{36} Furthermore, there is strong homology between the satellite sequences of acrocentric chromosomes and the subtelomeric repetitive sequences on some autosomes.\textsuperscript{37} It is possible that these variants arise from abnormal pairing and subsequent crossing over at meiosis between the satellites of acrocentric chromosomes and complementary subtelomeric sequences. Sequences similar to the D4Z4 complex repeat associated with FSHD, which maps to 4q35, are found on the
short arm of acrocentric chromosomes and it is of interest that chromosome 4 (4qs) is the most frequently described satellited variant chromosome.

Description and proper evaluation of these rare variants is vital when counselling subjects and families in whom a satellited chromosome is found, particularly when detected prenatally.

- We describe three apparently unrelated families in whom a translocation of a nucleolar organiser region (NOR) onto the short arm of chromosome 12 has been inherited through several generations.
- Conventional banding and FISH studies showed no detectable loss of material from this satellited chromosome (12p).
- There was no evidence of reproductive problems or phenotypic effects in the carriers of this satellited chromosome 12, indicating that it is a previously unreported variant chromosome.
