Serum Alkaline Phosphatase Types in North American Indians and Negroes

J. C. ROBINSON, C. LEVENE, B. S. BLUMBERG, and J. E. PIERCE

From the Biomedical Sciences Laboratory, Mental Retardation Program, National Institute of Child Health and Human Development, Bethesda, Maryland, and The Institute for Cancer Research, Philadelphia, Pennsylvania, U.S.A.

Recent investigations have revealed a correlation between human serum alkaline phosphatase types, the ABO blood groups, and the secretion of ABH substance in the saliva (Arfors, Beckman, and Lundin, 1963a, b; Shreffler, 1964; Beckman, 1964; Evans, 1965; Bamford, Harris, Luffman, Robson, and Cleghorn, 1965).

Arfors et al. (1963a) reported that phosphatase type 2 (Pp 2) was uncommon in people having blood group A. Beckman (1964) also demonstrated that the frequency of Pp 2 was correlated with the ABO blood groups, being present in 30% of group O and B subjects, 15% of AB, and only 2% of the A group. In contrast with results given by Shreffler (1964), Beckman did not find a significant difference in the frequency of Pp 2 between A_1 and A_2 subjects.

The association of phosphatase types with the secretor phenomenon was originally suggested by Arfors et al. (1963b) because of the highly significant correlation of phosphatase type with the Lewis red blood cell groups. It has been shown that in adults, Le (a-b+) subjects are salivary secretors on ABH substance; those who are Le (a+b-) are non-secretors; and those who are Le (a-b-) are usually, but not invariably, secretors (Race and Sanger, 1962). Arfors et al. (1963b) examined group O donors and found that the sera from all 16 Le (a+b-) subjects, presumably non-secretors, formed a single major zone in starch gel zymograms stained for phosphatases (phosphatase type 1, Pp 1). Of 41 sera from Le (a-b+) subjects, presumably secretors, 30 produced in addition a less rapidly migrating zone (phosphatase type 2, Pp 2). Shreffler (1964) found that amongst the secretors of ABH substances, Pp 2 was present in decreasing amount according to the ABO blood group: O or B > A_1. Little or none of the type Pp 2 was demonstrated in the serum from non-secretors.

No significant association exists between the phosphatase type and the following: sex, MNSs, Rh, Kell, Kidd, Lutheran, and P blood groups; and haptoglobin, Gm, and Gc serum protein types (Arfors et al., 1963a; Shreffler, 1964, 1965; Beckman, 1964). Shreffler (1965) found no association with the Duffy blood group; Beckman (1964), however, reported that the Pp 2 was higher in Fy (a+) subjects.

Association between serum alkaline phosphatase and blood groups has been demonstrated in cattle (Rendel and Gahne, 1963) and in sheep (Rendel and Stormont, 1964; Rendel, Aalund, Freedland, and Møller, 1964). A confirmation of this association in sheep, corroborated with family studies, was performed by Rasmussen (1965).

Robinson and Pierce (1964) demonstrated a differential susceptibility of the two phosphatase bands to the action of neuraminidase. The mobility of the fast band is decreased by incubation with neuraminidase; the mobility of the slow band is unaffected. The decrease of anodal migration results from a decrease in negative charge on the phosphatase as a consequence of the splitting off of neuraminic acid which has a free carboxyl group.

Using the neuraminidase technique, we examined serum samples from two American Indian populations (Montagnaise and Naskapi). Of the 267 sera examined, 10 contained a phosphatase band which, before incubation with neuraminidase, occupied the same zone as, and was indistinguishable from, the usual fast band. This component underwent a comparatively less marked decrease in mobility as a result of incubation with neuraminidase. It has been shown (Robinson, Pierce, and Blumberg, 1966) that this pattern is characteristic of a pregnancy-associated alkaline phosphatase, which has been
previously described by Boyer (1961), using a different technique. Variations of alkaline phosphatase seen in pregnant women have been studied by Beckman and Grivea (1965).

Materials and Methods

Serum Specimens. Blood samples were taken into sterile vacutainer tubes (Becton Dickinson Co.) containing no anticoagulant, and were stored at 4°C. The serum was separated within 4 days and stored in glass bottles at −20°C until tested.

Composition of the Populations

The Naskapi and Montagnais Indians. The Naskapi, Montagnais, and Eastern Crees who belong to the Algonkian linguistic group are found at present living in Quebec and Labrador. Most ethnologists consider that they have, in spite of their differences, an essential identity (Harper, 1964). These Indians never formed tribes in the usual sense, and formerly lived by hunting and fishing, each group breaking off into small bands of one or a few families, to wander in the region familiar to them.

The Montagnais occupied the St. Lawrence escarpment and the southern portion of the interior, and the Naskapis lived north of them as far as the forest extends. The two groups have been separated by the polarizing effect of the fur trade, and have grown apart by marked differences in cultural associations, education, acculturation, and religion. For about 300 years the Montagnais have been tributary to trading and mission stations along the shores of the St. Lawrence river. They are said to have a substantial admixture of European blood. Most are Roman Catholics and are literate in French as well as their own language. Before 1865, the Naskapis visited the St. Lawrence stations, but since that time they have depended almost exclusively on trading posts and missions operated by English-speaking persons in the region of Ungava Bay. Owing to this remoteness, there has not been any significant admixture with Europeans. They are literate in their own tongue, and have accepted the religion of the Anglican missions.

The establishment of an iron-mining centre in the interior of the Labrador Peninsula has had the effect of accidentally uniting the separated groups. Upon completion of a railway from Sept Iles to Schefferville, some 30 Montagnais families moved to Schefferville, and many commute seasonally according to opportunities of employment.

The Naskapis have been reduced in the past 150 years by starvation and disease. One remnant group hunted near Fort McKenzie, and when this closed in 1948 they moved to Fort Chimo. During the summer of 1956, due to the efforts of the Indian Affairs Branch of the Department of Citizenship and Immigration, the Naskapis moved to Schefferville and settled near the Montagnais. A preliminary language difficulty was readily overcome, but there has been little intermarriage between them owing chiefly to religious convictions strongly held by each group (Blumberg, Martin, Allen, Weiner, Vitagliano, and Cooke, 1964).

The Sapelo Island Negroes. Sapelo Island lies off the coast of Georgia and constitutes one of the 'Sea Island' group. The small (approximately 250) American Negro population who live there have had relatively little contact with the mainland until recent years. There have been very few inhabitants of European descent resident on the island and there is said to be little gene mixture in this group. They will be discussed in greater detail in a forthcoming monograph (Blumberg, 1967).

Of the approximately 200 Naskapis, 153 blood samples were collected, and of between 350 to 400 Montagnais, 114 blood samples were collected. 79 specimens of blood from the Sapelo Island community were examined.

Phosphatase Zymograms. Mixtures consisting of 0·05 ml. serum and an equal volume of Vibrio cholerae neuraminidase (Behringwerke, A.G., Marburg, Germany) were incubated 20 hours at 37°C. Horizontal starch gel electrophoresis (Smithies, 1955; Poulik, 1957) of the incubation mixtures was performed, together with corresponding serum samples. The phosphatase bands were more sharply defined when electrophoresis was limited to the time required for the brown 'borate-line' to reach 4·0–4·5 cm. beyond the insertions. The method for staining was the same as that used by Arfors et al. (1963a).

Blood Group and Secretion Typing. The typings for the blood groups and salivary secretion of ABH and Lewis substance were performed by Dr. Fred H. Allen, Jr., at the Blood Grouping Laboratory, Boston, Massachusetts. The blood groups of the Naskapi and Montagnais Indians were reported by Blumberg et al. (1964).

Results

The Figure shows the typical results of phosphatase groups in starch gel, both with and without prior treatment with neuraminidase. The frequency of phosphatase group 2 (Pp 2) in the Montagnais, Naskapi, and Sapelo populations is given in Table I.

The highest frequencies are in the Montagnais and Naskapi Indians, being 71·9% and 68·6%, respectively. The frequency of Pp 2 in the Sapelo population was 63·3%.

The results shown in Table II confirm the relation between the phosphatase groups and the ABO blood groups in all three populations we have examined.

In the Montagnais (total 114), 82 persons were found to belong to phosphatase group 2 (Pp 2), and
of these, 70 were of blood group O. A total of 153 persons was examined in the Naskapi, and of the 105 typed as Pp 2, there were 92 with blood group O. A similar state of affairs was seen in the Sapelo sample where out of a total of 78 persons examined, 49 were Pp 2, and 38 of these were group O.

This association between Pp 2 and the O blood group is more striking when all subjects with blood group A (A + AB) are compared with all those without blood group A (O + B). In each population sample a p value of <0.0005 was obtained.

Examination of the Lewis blood groups and ABH and Lewis secretion in the saliva (Table III) confirms the results of previous authors.

In the Montagnais and Sapelo Islanders the Pp 2 is absent or in low frequency in those people who are Le (a+b-) (p < 0.0005 and 0.005 > p > 0.001, respectively). There were no Le (a+b-) subjects amongst the Naskapi.

Results on ABH and Lewis secretion in the saliva are available for the Sapelo population only (Table IV).

There is an increased frequency of Pp 2 in ABH secretors (0.001 > p > 0.0005). There is also an increased frequency of Pp 2 in Lewis substance secretors, but the difference is not considered significant (0.05 > p > 0.25).

There was no association of the MNSs, Kidd (Jk), Sutter (Js), Xg, and Duffy (Fya) red blood cell groups, nor with the Gc serum group (Table V).

Montagnais examined directly Sapelo small populations Corcoran, and increased conspicuously high substance. frequency of group Le (and Boyd, 1963), borrow, ported an incidence of 27.5%, for Pp 2 in an adult Swedish population, and by Beckman (1964) who reported an incidence of 21.2% in adults, and 20.5% in children of a Brazilian population.

The reason for this difference in frequency is almost certainly due to two factors. The first is the increased frequency of blood group O in the populations under investigation (see Table II). This relatively high frequency of the blood group O in other Indian populations has been recorded (Gates, 1938; Matson and Piper, 1947; Boyd and Boyd, 1949; Chown and Lewis, 1956; Allen and Corcoran, 1960). The second reason lies in the high frequency of secretors in some Indian populations (Boyd and Boyd, 1949; Kaklamani and Holborow, 1963), and the high frequency of the blood group Le (a+b-) (and therefore the high frequency of secretors of ABH substance), in other Indian populations where secretor status was not directly examined (Chown and Lewis, 1956; Allen and Corcoran, 1960).

The problem of calculating gene frequencies in small populations was discussed by Neel, Salzano, Junqueira, Keiter, and Maybury-Lewis (1964) and Neel (1965). In this it was noted that the methods for calculating gene frequencies, whether applicable only to unrelated subjects or to family data, were based on the assumption that Hardy-Weinberg equilibrium pertained in the population. Neel emphasized that in calculating gene frequencies for such populations, the important question was not whether there was a departure from Hardy-Weinberg equilibrium conditions, but whether the departure was sufficient to introduce significant errors in calculations of gene frequencies which assume equilibrium. Examination of the MN groups in our three populations where phenotype accurately reflects genotype (i.e., M, MN, and N) showed a good fit to the Hardy-Weinberg expectations. As with Neel's population, this is surprising, as the populations we examined here may also violate some of the prerequisites for Hardy-Weinberg equilibrium (i.e., non-random mating, overlapping generations, and small population).

We have elected here, for the same reasons given by Neel et al. (1964) with his population of Xavante Indians, to calculate the frequency of Pp 2 in these three populations as if they were composed of unrelated people drawn from populations of infinite size in Hardy-Weinberg equilibrium.

Our observations on the ABO and Lewis blood

**Discussion**

The frequency of phosphatase group 2 (Pp 2) is conspicuously increased in all of our three populations (Montagnais, Naskapi, and Sapelo) when compared to those reported by Arfors et al. (1963a), with an incidence of 27.5%, for Pp 2 in an adult Swedish population, and by Beckman (1964) who reported an incidence of 21.2% in adults, and 20.5% in children of a Brazilian population.
groups, and ABH secretion in the saliva, confirm
the previous observations of Arfors et al. (1963b),
Beckman (1964), Shreffler (1965), Evans (1965), and
Bamford et al. (1965). The association of Pp 2
with the ABO blood groups is seen in all three
populations, and with the ABH secretor system in
the Sapelo population. Our sample also serves to
emphasize that these effects are not absolute and that
Pp 2 was detected in some persons of blood group
A and also in some persons who were non-secretors
of ABH in their saliva.

No association was found between the Duffy
blood group (Fy*) and phosphatase groups in the
three populations examined. This confirms the
result of Shreffler (1965), who did not find any
association, but it is contrary to that of Beckman
(1964) who found a higher phosphatase 2 (Pp 2)
amongst subjects with the Duffy blood group.

The first highly significant association at the
enzyme level has been demonstrated in the recent
investigations of the ABO blood groups in relation
to types of serum alkaline phosphatase (Brit. med.
J., 1965). Not only have associations of the differ-
tent types of serum alkaline phosphatase been ob-
served, but also quantitative variations. Bamford et
al. (1965) have shown that in blood groups O and B,
with red cells Le (a −) — mostly secretors of ABH
substance — the average level of serum alkaline
phosphatase is 15% higher than in blood groups A
and AB. This quantitative increase of alkaline
phosphatase, as shown by Bamford et al. (1965),
adds support to the hypothesis that the origin of the
two types of alkaline phosphatase, fast moving and
slow moving, are different, and that in Pp 2, where
both bands are present, one would expect, on the
average, higher values for levels of alkaline phos-
phatase. Evidence has been presented by Cunning-
ham and Rimer (1963), Haije and De Jong (1963),
Fishman and Kreisher (1963), and Hodson, Latner,
and Raine (1962), that the fast-moving phos-
phatase band present in all individuals is produced in
the liver, and that the slow-moving phosphatase
band, present only in some subjects, is produced in
the jejunal mucosa.

These findings are consistent with the concept
that the statistical relation between duodenal ulcer
and blood group O may be related to the presence
of a different enzyme system in the jejunum, and not
directly to the ABO blood group system.

Summary
Serum alkaline phosphatase variations were
examined on specimens from three populations,
Montagnais and Naskapi Indians, and Sapelo
Island Negroes, by starch gel electrophoresis.

The action of neuraminidase on the phosphatase
bands is presented, and the presence of a pregnancy
band was demonstrated in 10 of the persons in-
vestigated from the Montagnais and Naskapi.

The frequency of phosphatase 2 (Pp 2) was
71.9% in the Montagnais, 68.6% in the Naskapi,
and 63.3% in the Sapelo Island Negroes.

Confirmation of the association between the ABO
blood groups and salivary ABH secretor phenotypes
with serum alkaline phosphatase was obtained.

No association was observed of the MNs, Kidd
(Jk), Sutter (Js), Xg, and Duffy (Fy*) red cell
groups, nor with the Gc serum groups, and the
phosphatase groups in the three populations
examined.
