Background: BRCA1 is a tumour suppressor with pleiotropic actions. Germline mutations in BRCA1 are responsible for a large proportion of breast-ovarian cancer families. Several missense variants have been identified throughout the gene but because of lack of information about their impact on the function of BRCA1, predictive testing is not always informative. Classification of missense variants into deleterious/high risk or neutral/low clinical significance is essential to identify individuals at risk.

Objective: To investigate a panel of missense variants.

Methods: To investigate a panel of missense variants, we used a comprehensive framework that included (1) a functional assay based on transcription activation; (2) segregation analysis and a method of using incomplete pedigree data to calculate the odds of causality; (3) a method based on interspecific sequence variation. It was shown that the transcriptional activation assay could be used as a test to characterise mutations in the carboxy-terminus region of BRCA1 encompassing residues 1396–1863. Thirteen missense variants (H1402Y, L1407P, H1421Y, S1512I, M1628T, M1628V, T1685I, G1706A, T1720A, A1752P, G1788V, V1809F, and W1837R) were specifically investigated.

Conclusions: While individual classification schemes for BRCA1 alleles still present limitations, a combination of several methods provides a more powerful way of identifying variants that are causally linked to a high risk of breast and ovarian cancer. The framework presented here brings these variants nearer to clinical applicability.

Individuals carrying inactivating germline mutations in the breast and ovarian cancer susceptibility gene BRCA1 have an increased risk of developing cancer, making it essential to identify those at risk. This task is complicated by the presence of over 1000 different BRCA1 alleles in the population carrying nonsense, missense, frameshift mutations as well as large and small deletions (Breast Cancer Information Core, BIC: http://research.nhgri.nih.gov/bic/).

Progress has been made recently in identifying which alleles are likely to be associated with disease. Several lines of evidence derived from population based analysis and functional studies indicate that all mutations leading to premature termination are associated with increased cancer susceptibility. However, missense mutations still pose an important problem for risk assessment because of their low frequency and, in some cases, ethnic specificity, which make population based studies difficult. Over 300 missense sequence variants have been identified in BRCA1, located throughout the gene (BIC database). In breast-ovarian cancer families in which a missense variant is the only sequence alteration detected, it is difficult to determine whether the variant is causally linked to predisposition or not and so it is uninformative for predictive testing purposes.

Functional studies in which specific activities of the protein or broad biological phenotypes are assayed have contributed to the classification of missense variants. When integrated with population based studies, functional tests can be a powerful method to help characterise these variants. BRCA1 is involved in maintaining genomic stability and participates in the DNA damage response, but its biochemical functions have remained elusive. The BRCA1 protein contains several motifs and structural domains that have been functionally characterised or, in some cases, inferred from sequence analysis and prediction. A zinc binding RING finger, which binds the BRCA1 associated RING domain protein BARD1 is present at the N-terminal region (aa 24–64). The BRCA1–BARD1 complex behaves as an E3 ubiquitin ligase. Cancer associated missense mutations that are located in this region disrupt BRCA1–BARD1 interaction and affect its in vitro ubiquitination activity. At the C-terminus, two BRCT domains in tandem (BRCT-N: aa 1653–1736; BRCT-C: aa 1760–1855) display a transcription activation function when fused to a heterologous DNA binding domain and mediate the interaction of BRCA1 with the RNA polymerase II holoenzyme. BRCT domains are protein–protein interaction domains found in proteins involved in DNA repair and cell cycle control. Mutations that result in the truncation or structural alteration of the BRCT segment have been identified in hereditary breast–ovarian cancer families, showing the essential nature of this portion of the gene (BIC database). Importantly, cancer associated missense mutations located at the BRCT domains abolish its transcription activity in an artificial system. The strong correlation between cancer association and disruption of a certain biochemical function, even though determined in an artificial system, suggest that specific biochemical tests are powerful tools to characterise these variants.

We and others have characterised several missense variants located at the BRCT domains using a transcription activation assay. While the published data on BRCA1 suggest a (direct or indirect) function in transcription, it is unlikely that BRCA1 represents a bona fide transcriptional activator. Our working model is that the transcription assay is.

Abbreviations: DBD, DNA binding domain
a monitor of the integrity of the C-terminal domain of BRCA1 and therefore can be used to derive functional information. Along those lines, we hypothesised that unclassified missense variants located in regions of BRCA1 that contribute to transcription activation besides the BRCT domains might be amenable to a transcription based classification. In the present study we show that the transcriptional activation assay can be used as a test to characterise mutations in the region encompassing aa 1396–1863 (exons 13 to 24) and we specifically investigated 13 missense variants (H1402Y, L1407P, H1424Y, S1512I, M1625T, M1628T, M1628V, T1685I, G1706A, T1720A, A1752P, G1788V, V1809F, and W1837R). In addition, we analysed all the mutations using a prediction algorithm based on interspecific sequence variation and Grantham matrices. Pedigrees were also analysed for segregation analysis, and posterior probabilities were calculated to determine the odds of causality for each variant. Finally, co-occurrence of the variant with other known deleterious mutations was taken into account. These results were combined with previously published results derived from methods including a prediction algorithm based on general protein structure parameters that evaluates the impact on function for mutations at the BRCT domain,23 and a protease based assay.20 This integrated approach provided us with a cross validated scheme to classify variants as well as to identify the strengths and limitations of current methods.

METHODS

Constructs

Wild type GAL4 DNA binding domain (DBD) fusion construct aa 1560–1863 of human BRCA1 in pGB9 (Clontech) was previously described.4 The following wild type BRCA1 fragments were amplified by polymerase chain reaction (PCR) using the plasmid pcBRCA1-385 (a gift from drifts, National Human Genome Research Institute) as a template and the following nucleotide primers: 2–11B (aa 1–323) (ZNF2F, 5′GCGGATCCATCGGGGAAACCATGCGG 3′; BRAL, 5′GATGGAAGCCCTTCTGCTCTT 3′), 13–21 (aa 1396–1778) (UX13, 5′ATAGTCGACTTCCAGCCCA 3′; BRAL, 5′ATATGCTGCTCTGCTCTT 3′), 14–24 (aa 1455–1863) (UX14, 5′CCAGGAATCTCCAGAAGAAAGTGTGATGCTGCTCTTCT 3′; 24ENDT); H1421Y 5′ region (H1421Y-L, 5′AGAAGCTCGGCTCCATCACCTGTTCTCAAAC; UX13); S1512I 5′ region (S1512I-U, 5′GGGACGCTATGGTTCCGGGAGCCAGCCTTCTCGTTCTCT 3′; 24ENDT); P1614S 5′ region (P1614S-L, 5′GCAGGCTATGGTTCCGGGAGCCAGCCTTCTCGTTCTCTC 3′; 24ENDT); P1614S 5′ region (P1614S-L, 5′GCAGGCTATGGTTCCGGGAGCCAGCCTTCTCGTTCTCTC 3′; 24ENDT); M1628V 5′ region (M1628VR-L, 5′GGCGGCTATAATGCAGTGGAAGAAAGTGTGATGCTGCTCTTCT 3′; 24ENDT); M1628V 5′ region (M1628VR-L, 5′GGCGGCTATAATGCAGTGGAAGAAAGTGTGATGCTGCTCTTCT 3′; 24ENDT); L1407P-L, 5′GACTTGGAGCCCTGGTTCTTTGGACCTTGGGAATCCCAGGAC 3′; 24ENDT); M1628V 5′ region (M1628VR-L, 5′GGCGGCTATAATGCAGTGGAAGAAAGTGTGATGCTGCTCTTCT 3′; 24ENDT); A1752P 5′ region (A1752PF-L, 5′CCATTTTCCGCCGGCAATTGGTCCTGGGATTCTCGAGGTCGCTTTGGACCTTGGGAATCCCAGGAC 3′; 24ENDT); M1628V 5′ region (M1628VR-L, 5′GGCGGCTATAATGCAGTGGAAGAAAGTGTGATGCTGCTCTTCT 3′; 24ENDT); T1700A 5′ region (T1700A-U, 5′ATATCCATGGTGGCCCG TTACAGCAACACAC; UX13); T1720A 5′ region (T1720A-U, 5′ATATCCATGGTGGCCCG TTACAGCAACACAC; UX13). Amplification was carried out using the Quickchange II site directed mutagenesis kit (Stratagene) on a monitor of the integrity of the C-terminal domain of BRCA1 UAS, which is recognised by GAL4 DNA binding domain (DBD). EGY48 cells were transformed with plasmid reporters.

Transcription assay in yeast

Two Saccharomyces cerevisiae strains were used: EGY48 [MATα, ura3, trp1, his3, 6 lexA operator-LEU2] and SFY526 [MATa, ura3-52, his3-200, ade-2-101, lys-s-801, trp-1-901, leu 2-3, 112, can2, gal-4-542, gal 8-538, URA3::GAL1-lacZ].2,7 SFY526 cells contain a lacZ reporter gene under the control of GAL1 UAS, which is recognised by GAL4 DNA binding domain (DBD). EGY48 cells were transformed with plasmid reporters.
Transcription assay in mammalian cells

We used pG5Luc, which contains a firefly luciferase gene under the control of five GAL4 binding sites, as a reporter for the assay. Transfections were normalised with an internal control pHGR-TK (Promega), which contains a Renilla luciferase gene under a constitutive TK basal promoter using a dual luciferase system. Human 293T cells were cultured in Dulbecco’s modified Eagle’s medium (DMEM) supplemented with 5% calf serum and plated in 24-well plates the day before transfection. Transfections were done in triplicate using Fugene 6 (Roche) and harvested 24 hours post-transfection. Cells were lysed in RIPA buffer (150 mM NaCl, 10 mM Tris-HCl pH 7.4, 5 mM EDTA, 0.1% sodium dodecyl sulphate, 1% Triton X-100, 0.1% sodium deoxycholate). The blots were incubated with α-GAL4 DBD monoclonal antibody (Clontech). Lysates were cleared and samples were separated on 10% SDS-PAGE; equal amounts of protein were loaded for every sample. Gels were electroblotted on a wet apparatus to a polyvinylidene difluoride (PVDF) membrane and probed with an α-LexA DBD monoclonal antibody (Clontech).

Our laboratory has completed the analysis of 27% of the existing unclassified variants (32/117) in the C-terminus of BRCA1 (residues 1560–1863). To validate the assay we have used (a) all the unambiguously classified missense variants, and (b) all other variants for which there are strong (but not definitive) clinical data. Using the set of variants in (a), the assay correctly classified the four variants that can be classified unambiguously as deleterious (A1708E, R1699W, M1775R) or benign (S1613G) based on clinical data. Using the set of variants in (b), the assay correctly classified all nine other variants with strong supporting clinical evidence for classification. These results suggest a high sensitivity and specificity for this assay.

RESULTS

Frequency in control populations

Six variants (G1706A, A1708E, A1752P, M1775R, G1788V, and W1837R) were assessed using PCR/LDR followed by assessment in a DNA microarray in 500 healthy women without cancer of varying ages (18–40 years) and ethnic groups. All were at a frequency of 0/500. The remaining variants were assessed by denaturing gradient gel electrophoresis (DGGE) with the following frequencies: H1402Y (20/500), A1455–1559 (6/500), S1613G (260/500), M1628V (0/500), M1628T (0/500), T1685I (0/500), L1407P (0/500), H1421Y (0/500), S1512I (6/500), and S1505H (15/500). The results in a mammalian expression system confirmed those obtained in yeast, with construct aa 1396–1863 showing the highest activity (fig 1C).

Functional analysis of missense variants

The location of the 13 missense variants studied as well as the negative and positive controls are indicated by arrows in fig 2A. Seven variants lie in the BRCT domains. Six of the variants lie upstream of the BRCT domains, three of which lie within the putative coiled coil domain (fig 2A). Three known BRCT deleterious/high risk variants—A1708E, M1775R, and Y1853X—were used as negative (that is, loss of function) controls, and S1613G (a common neutral polymorphism) and wild type BRCA1 (aa 1396–1863) were employed as positive controls. Results show that both in yeast and mammalian cells the three negative controls located in the BRCT domain lose most of transcription activation function consistent with a loss of function mutation, whereas the positive control, S1613G had an activity equal to or higher than the wild type, as observed previously (fig 2B and 2C). Seven unclassified missense variants in the BRCT domains (T1685I, G1706A, T1720A, A1752P, G1788V, V1809F, and W1837R) were then tested. Variants T1685I, A1752P, G1788V, V1809F, and W1837R showed greatly decreased transcription activation.
levels (at least \(<50\%\)) both in yeast and mammalian cells, comparable with the known mutant controls and consistent with their classification as deleterious/high risk variants (fig 2B and 2C).

Variants G1706A and T1720A showed slightly reduced transcription activation levels in yeast cells, at 64\% and 74\%, respectively, of the wild type control. Interestingly, whereas T1720A had activity comparable to wild type in mammalian cells, G1706A showed a markedly reduced activity. The intermediate results for these mutants suggest that they may represent moderate rather than high risk variants.

Six additional variants (H1402Y, L1407P, H1421Y, S1512I, M1628T, and M1628V) in locations outside the BRCT domains were also investigated for their effect on transcription. Three of the variants were located in a region in which a putative coiled coil domain has been predicted to form (fig 2A). Variant L1407P showed significantly reduced transcription activation levels consistent with a high risk mutation (fig 2B, 2C). Variants H1402Y, H1421Y, and S1512I showed transcription activation levels equal to or higher than wild type BRCA1, suggesting that they do not represent high risk variants and are likely to have low clinical significance.

In yeast cells, protein levels were slightly variable in three independent clones. Most variants displayed levels comparable to wild type, with the exception of Y1853X and T1685I, which showed markedly reduced levels suggesting that protein instability might be the underlying cause of loss of function. In mammalian cells, some variants (S1512I, V1809F, and W1837R) had markedly reduced levels. However, no loss of function variant showed consistently reduced levels in yeast and mammalian cells, suggesting that even when expressed at higher levels they were unable to activate transcription (fig 2D).

**Pedigree analysis**

In order to obtain additional information to classify the missense variants we applied a recently developed full likelihood method for the evaluation of causality from family data.\(^32\) For the analysis of co-segregation we assumed an allele frequency of the variant of 0.0001 and a penetrance model with separate age specific risks of breast and ovarian cancer for BRCA1 based on meta-analysis estimates.\(^33\) We obtained six pedigrees for five variants (M1628T, G1706A, T1720A, V1809F, and W1837R) (fig 3). For M1628T we obtained odds against causality of 10.4:1, consistent with the data obtained in the functional assay. For G1706A we obtained odds against causality of 1.3:1. This rather uninformative result reflects the fact that this large pedigree with multiple cases typed had one case diagnosed at age 53 that did not carry the variant. This result may also reflect the
fact that G1706A may be a moderate rather than a high risk variant. For variant V1809F the odds in favour of causality were 7.3:1, consistent with the functional test, suggesting that it is a high risk variant. Two pedigrees were analysed for the T1720A variant generating combined odds against causality of 355:1. This result is also consistent with the functional data and suggests that T1720A represents a neutral/low clinical significance variant. For variant W1837R we obtained odds of 4:1 against causality, which contradicts our functional data.

Analysis of interspecific sequence variation

In order to determine further the likelihood that a particular variant may or may not represent a high risk variant we also analysed the amino acid substitution using a modified Grantham matrix, adapted for BRCA1.23 These results are shown in table 1. The classification based on interspecific sequence variation confirms our choice of controls, with S1613G being classified as neutral and M1775R, A1708E, and Y1853X being classified as deleterious. It also confirms our functional results for H1402Y, L1407P, T1685I, G1706A, G1788V, and W1837R. Variant M1628V, however, was classified as a neutral/low risk variant in contradiction of our functional results. The remaining variants could not be classified by this method.

Co-occurrence with deleterious mutations

Homozygous disruption of Brca1 in mouse resulted in embryonic lethality (reviewed by Brodie and Deng44). In addition, there is a deficit from expected numbers of BRCA1 homozygotes and compound heterozygotes for deleterious mutations among individuals with the founder mutations 185delAG and 5382insC.45 This led to the notion that if an unknown variant co-occurs with a known deleterious mutation it is unlikely that this variant is a high risk one. Co-occurrence data relative to a set of 40 000 individuals (kindly provided Amie Deffenbaugh, Myriad Genetics Laboratories Inc) are listed in table 1. Variants H1402Y, S1512, and M1628T co-occur with a deleterious mutation and are therefore unlikely to represent high risk variants, a result supported by the functional assays.

DISCUSSION

In order to provide a more informative risk assessment for individuals carrying a mutation in BRCA1 we used several approaches, including association studies and segregation
classification of BRCA1 missense variants of unknown clinical significance

One method of classification of a BRCA1 variant is the transcription functional assay. We have previously shown that alleles containing neutral polymorphisms retained wild type activity in transcription. Several lines of evidence have pointed to a physiological role of BRCA1 in transcription, although its exact biochemical function is unclear. However, regardless of whether or not BRCA1 acts as a transcription activator in vivo, we have proposed that a transcription assay using a heterologous DNA binding domain fusion and a reporter gene serves as a monitor of the integrity of the C-terminal region of BRCA1. Because this region is essential for the tumour suppressive function of BRCA1, the transcription assay is able to generate information about the impact of missense changes. Previously, this assay was only applicable to variants in the BRCT domain (exons 16–24). Here we show that regions adjacent to the BRCT domains contribute to full activity in transcription, allowing us to extend our analysis to encompass exons 13–24. Once it was verified that the extended assay assigned positive and negative controls correctly, seven missense variants were tested (fig 2). The variants were chosen because they were identified as the sole BRCA1 alteration in individuals considered to be at high risk for breast or ovarian cancer (S1512I, M1628V, M1628T, T1685I, G1706A, T1720A, A1752P, G1788V, V1809F, and W1837R) or were located at or in close proximity to the putative coiled-coil domain (H1402Y, L1407P, and H1421Y).

Seven of the variants caused a dramatic loss of the transcription activation function (L1407P, M1628V, T1685I, A1752P, G1788V, V1809F, and W1837R), similar to known high risk mutation controls, suggesting that they may constitute deleterious/high risk variants (fig 2B and 2C; table 1). Four of the variants (H1402Y, H1421Y, S1512I, and M1628T) showed transcription activation similar to or greater than the wild type BRCA1, suggesting they are probably neutral/low clinical significance variants. The two remaining variants had intermediate results. G1706A showed a slightly reduced activity in yeast but a markedly reduced activity in mammalian cells. Variant T1720A had a slightly reduced activity in yeast and but activity comparable to wild type activity in transcription.

The occurrence of the variant in high risk individuals (affected by breast or ovarian cancer and with a family history of breast or ovarian cancer) compared with controls can provide clues as to its risk or neutral/low clinical significance. The occurrence of the variant in the status, but the frequencies of variants differ considerably between ethnic groups. Segregation of the variant in the BRCT domain and six variants outside the BRCT domain were tested (fig 2). The variants were chosen allowing us to extended our analysis to encompass exons 13–24. Once it was verified that the extended assay assigned positive and negative controls correctly, seven missense variants of unknown clinical significance were tested. Previously, this method was only applicable to variants in the BRCT domain. Here we show that regions adjacent to the BRCT domains contribute to full activity in transcription, allowing us to extend our analysis to encompass exons 13–24. Once it was verified that the extended assay assigned positive and negative controls correctly, seven missense variants were tested (fig 2). The variants were chosen because they were identified as the sole BRCA1 alteration in individuals considered to be at high risk for breast or ovarian cancer (S1512I, M1628V, M1628T, T1685I, G1706A, T1720A, A1752P, G1788V, V1809F, and W1837R) or were located at or in close proximity to the putative coiled-coil domain (H1402Y, L1407P, and H1421Y).

Seven of the variants caused a dramatic loss of the transcription activation function (L1407P, M1628V, T1685I, A1752P, G1788V, V1809F, and W1837R), similar to known high risk mutation controls, suggesting that they may constitute deleterious/high risk variants (fig 2B and 2C; table 1). Four of the variants (H1402Y, H1421Y, S1512I, and M1628T) showed transcription activation similar to or greater than the wild type BRCA1, suggesting they are probably neutral/low clinical significance variants. The two remaining variants had intermediate results. G1706A showed a slightly reduced activity in yeast but a markedly reduced activity in mammalian cells. Variant T1720A had a slightly reduced activity in yeast and but activity comparable to wild type BRCA1 in mammalian cells. Based on the results obtained we would tentatively classify T1720A as a neutral/low clinical significance variant. At this point we cannot classify variant G1706A. We then carried out an analysis using interspecific variation, pedigree analysis, and co-occurrence data (table 1). Of the seven variants for which the method based on interspecific variation was able to reach a conclusion, the data confirmed the classification based on our functional tests in six cases (L1407P, H1402Y, T1685I, G1706A, G1788V, and W1837R) but presented a contradiction for variant M1628V. The pedigree analysis confirmed our results for...
three of the four variants analysed. Results from pedigree analysis for W1837R contradicted all the other methods, although the odds against causality were rather small. Interestingly, results for G1706A suggested again that the available information is not enough to classify it. While no conclusion can be drawn for variants that have very low frequency and are not found to co-occur with a deleterious mutation (for example, L1407P and H1421Y), co-occurrence data indicated that H1402Y, S1512, and M1628T do not co-occur with a deleterious BRCA1 mutation in 40,000 samples (Myriad Genetics Laboratories). Number of times this variant has been reported to the BIC database as of August 2004. Number of times this variant has been observed co-occurring with a known deleterious BRCA1 mutation in 40,000 samples (Myriad Genetics Laboratories). * Nucleotide numbering corresponds to human BRCA1 cDNA deposited in GenBank accession number U14680. † Amino acid residues present at the same position in the BRCA1 orthologs. The multiple sequence alignment of orthologous BRCA1 BRCT domains from eight species, including Homo sapiens (GenBank accession number U14680), Pan troglodytes (AF207822), Mus musculus (U50709), Canis familiaris (AF355273), Gallus gallus (AF355273), Xenopus laevis (AF416868), and Tetraodon nigroviridis (AY428536), was obtained by using program MegAlign (Clustal W). ¶ Nucleotide numbering corresponds to human BRCA1 cDNA deposited in GenBank accession number U14680. ‡ Pedigree analysis. § Transcript analysis. ¶ Pedigree analysis. ** Protease sensitivity; data from Williams et al. 39 †† Structure based prediction; data from Mirkovic et al. 41 ‡‡ Number of times this variant has been reported to the BIC database as of August 2004. §§ Number of times this variant has been observed co-occurring with a known deleterious BRCA1 mutation in 40,000 samples (Myriad Genetics Laboratories). * According to prediction by the Paircoil scoring form (http://paircoil.cs.ucd.ie/cgi-bin/paircoil). 42 ○, neutral/low clinical relevance; ●, moderate to low risk variant; ●●, deleterious/high risk variant; n/a, not determined; na, not applicable; ?, unclassified.
based on the fact that variants that cause conformation changes are more likely to be prone to proteolytic degrada-
tion.33 For all five of the variants analysed by this method (T1720A, A1752P, G1788V, V1809F, and W1837R), protease sensitivity correlated with abrogation of transcriptional activation. We also compared our data with results derived from a method based on protein structure parameters to predict the outcome of different variants of BRCA1.24 For the seven variants for which there is a prediction, six (T1685I, G1706A, T1720A, A1752P, G1788V, and W1837R) confirmed the results obtained. In fact, the G1706A variant was considered not explained by the algorithm because the qualitative yeast data used to test G1706A indicated wild type function while the algorithm predicted a functional impact. It is possible that G1706A may represent a moderate/low risk variant and our current methods are not yet powerful enough to recognise this variant. Variant V1809F was contradictory; however, given that fact that pedigree analysis, transcriptional activation, and protease sensitivity indicate a high risk variant, our conclusion is that, although the change is a conservative one, the side chain size threshold in the algorithm needs to be refined. In summary, we have classified six missense variants (L1407P, M1628V, T1685I, A1752P, G1788V, and V1809F) as probably deleterious/high risk variants and the remainder as probable neutral/low clinical significance variants (H1402Y, H1421Y, S1512L, M1628T, and T1720A), with two variants (G1706A and W1837R) left unclassified.

Previously, all the known deleterious missense changes were in the RING domain or BRCT repeats. Although further work is needed to classify variants L1407P and M1628V unambiguously, our results provide evidence that other regions or motifs are likely to harbour high risk missense substitutions. In particular, classification of L1407P as a high risk variant suggests an important function for the putative coiled coil motif as suggested previously.11,13 The 4-3 spacing of hydrophobic residues in the coiled coil is clearly evolutionarily conserved through the puffer fish BRCA1 sequence (Tetraodon, accession YA428356).

Conclusions
While individual classification schemes for BRCA1 alleles still present limitations and no single method can reliably be used alone, a combination of several methods may provide a more powerful way of identifying variants that are causally linked to a high risk of breast and ovarian cancer.30 The framework presented here pushes our understanding of these variants further towards clinical applicability in the near future.

ACKNOWLEDGEMENTS
We thank Qun Wang for excellent technical assistance and Barbara Pasini (University of Torino) for additional pedigreed information.
