The gr/gr deletion(s): a new genetic test in male infertility?

C Giachini, E Guarducci, G Longepied, S Degr’Innocenti, L Becherini, G Forti, M J Mitchell, C Krausz

Y chromosome microdeletions are the most frequent genetic cause of severe oligozoospermia (<5 million spermatozoa/ml) and azoospermia (absence of spermatozoa in the ejaculate). Microdeletions associated with infertility occur in specific regions of the long arm of the Y chromosome, called azoospermia factor (AZF) regions. In 1996, three types of AZF deletion (AZFa, AZFb, and AZFc) were described by Vogt et al; however, after the complete physical map and sequence of the AZFb and AZFc regions was produced, it became evident that the AZFb and AZFc intervals partially overlap. The Y chromosome is extremely rich in repetitive sequences, organised in amplicons. Ampliconic sequences are characterised by sequence pairs showing nearly complete (>99.9%) nucleotide identity, organised in massive palindromes. These repeated sequences may undergo genetic exchange through gene conversion—that is, non-reciprocal transfer of sequence information occurring between duplicated sequences within the chromosome, a process that could account for the >99.9% nucleotide identity between the arms of a palindrome. Although this mechanism may serve to preserve Y chromosome genes from the gradual accumulation of deleterious mutations and thus prolong their genetic fitness, this peculiar organisation also provides the structural basis for deletions and rearrangements.

The classical AZFc deletion, which removes 3.5 Mb between the b2/b4 amplicons, is the most frequent type of deletion. Taking into consideration the Y chromosome structure and the suggested deletion mechanism, a number of other possible partial deletions have been proposed in both the AZFb and AZFc regions. The frequency and the pathological significance of these partial deletions is not yet clear, although recently a partial deletion termed gr/gr has been described specifically in infertile men with varying degrees of spermatogenic failure. This deletion removes half the AZFc gene content, including two copies of the major AZFc candidate gene called DAZ. Another deletion, named b2/b3 or u3-gr/gr, removes a similar quantity of AZF genes, seems to have no effect on fertility status in association with a certain Y chromosome background commonly present in northern Eurasian populations (Y haplogroup N). A similar conclusion can also be drawn for the gr/gr deletion found in association with Hgr D2b, which is present in 20% of Japanese men. One of the possible explanations for the heterogeneous phenotype observed in men with the deletion is that the type and number of missing gene copies or other unknown Y chromosome related factors (for example duplications or beneficial mutations in other parts of the Y chromosome) may also influence the phenotype.

The aims of this study were: (a) to establish the clinical significance of partial AZFc deletions (that is, if any of them are specific for spermatogenic failure or can be considered a risk factor); and (b) to gain insight through a combined approach (quantitative and qualitative analysis of DAZ and CDY, definition of Y chromosome haplogroup, and mutation analysis of DAZL in men with partial AZFc deletion) into the molecular basis of the heterogeneous phenotype described in men bearing partial AZFc deletions.

### MATERIALS AND METHODS

#### Subjects
The study population consisted of 150 infertile patients (89 idiopathic and 61 with mild abnormal andrological findings: varicocele, monolateral cryptorchidism, recurrent infections) seeking complete andrological investigation for couple infertility at the Andrology Unit of the University Hospital Careggi in Florence, Italy, and 189 normospermic controls from the Andrology Unit of the University Hospital Careggi in Florence, Italy.

#### Abbreviations
- AZF, azoospermia factor; SFV, sequence family variant; SNV, single nucleotide variant; STS, sequence tagged site; SFV
Italian origin. Cytogenetic analysis and Y chromosome microdeletion screening revealed 46,XY karyotype and the absence of AZF microdeletions in all included patients. Samples were collected using approved protocols and the informed consent of all individuals was obtained.

Screening for partial AZFc deletions

We tested eight STSs, originally described by Repping et al: sY1291, sY1191, sY1161, sY1206, sY1201, sY142, sY1258, and sY1197. In addition, we tested our samples with a complementary set of primers, o1084/1085 and o1276/1277. We identified gr/gr deletion by the following STS results: sY1291 and o1084/85 negative; sY1161, sY1191, sY1206, sY1201, and o1276/1277 all positive (an example of a PCR duplex result is shown in fig 1). The b2/b3 or u3-gr/gr deletion is characterised by the absence of the STS sY1191-o1276/1277 and the presence of the rest of the STS.

For DAZ, we chose the sequence family variant (SFV) at STS sY587 in intron 10, which distinguishes DAZ1/2 from DAZ3/4.

For CDY1 we used a C/A SFV situated 7770 bp 5' of the CDY1 translation start codon (CDY7750). In order to quantify copy number we used a PCR based method described by Machev et al. The PCR products were separated on an automatic sequencer (LI-COR Gene ReadIR 4200), and quantification was performed by ONE-Dscan.

Y chromosome haplotyping

Y chromosome haplotyping was performed as previously published for the YAP, M9, SRY4064, and 92R7 polymorphisms. The Tat polymorphism was assayed by PCR digestion with primers o1489: atgtataagtgcttgtg and o1490: gtagataattgagaag.tc (annealing 54°C). The 12f2 assay was performed as a duplex with 5RY primers 3'SRY15 and 3'SRY16 and the 12f1 primers 12f1D and 12f1E. These primer pairs were used at a concentration of 300 nmol/l for each 5RY primer and 600 nmol/l for each 12f1 primer, and the annealing temperature used was 52°C. Polymorphisms were visualised by restriction enzyme digest for M9 (HincII), SRY4064 (BsrBI), Tat (HpyCHIV), and 92R7 (HindIII).

All men were haplotyped for YAP, 12f2, and 92R7 polymorphisms (table 1), and individuals with partial AZF deletions were further genotyped with the Tat, M9, and SRY-4064 SNPs, defining five haplogroups, E, J, and K (xN3, P), N3, and P, and one paragroup Y*(xD, E, J, K).

Statistical analysis

Statistical analysis was performed using the statistical package SPSS for Windows (version 11; SPSS, Chicago, IL, USA). We tested the significance of the observed difference in the incidence of gr/gr deletion between our infertile and control populations using Fisher's exact test. Our null hypothesis was that incidence is the same in infertile and control populations. All variables were checked for normal distribution by Kolmogorov-Smirnov one sample test. For comparisons of means between groups of different genotypes, Student's t test for independent samples, when normal distribution was observed, was applied. Logarithmic transformation of data was performed in order to normalise the distribution when the presence of log normal distribution was checked. Finally, in case of non-normalised distribution, the non-parametric Mann-Whitney U test was applied to achieve the same objective. A p value <0.05 was considered statistically significant for each test.

RESULTS

Frequency and type of partial AZFc deletions in patients and normospermic men

Based on the STS +/- analysis, it was possible to distinguish between different types of partial deletions (fig 1). We found two types of partial AZFc deletions: gr/gr (8/339) and the b2/b3 (3/339) deletion, whereas b1/b3 was absent in our study population.

The gr/gr and b2/b3 deletions were found in both the infertile and normospermic groups, although at different frequencies. The frequency of gr/gr deletions was significantly higher in the patient (8/150; 5.3%) than in the normospermic group (1/189; 0.5%) (p<0.012; odds ratio (OR) 10, 16; 95% confidence interval (CI) 1.28 to 80.3). In contrast, the frequency of the less common b2/b3 (u3-gr/gr) deletion was not different between the two groups (1.3% v 0.5%; p = 0.41).

DAZ and CDY1 gene copy definition

In order to further characterise the deletions, we defined the type of missing DAZ (DAZ1/DAZ2/DAZ3/DAZ4) and CDY1 (CDY1a/CDY1b) gene copies. In the gr/gr deletion group, we found three types of deletion pattern: DAZ1/DAZ2+CDY1a, DAZ3/DAZ4+CDY1a, and DAZ3/DAZ4+CDY1b (fig 2). In the b2/b3 deletion group, we found two types of deletion pattern: DAZ3/DAZ4+CDY1a and DAZ3/DAZ4+CDY1b. The presence of different gene copy deletions patterns (five combinations found in our study) indicates that each type of partial deletion may be further divided into subtypes, and although the number of gene copies removed is the same, the missing copy type is different.

Interestingly, DAZ1/DAZ2 and CDY1a were deleted only in the patient group, whereas DAZ3/DAZ4 and CDY1b were deleted in both groups. However, the deletion of CDY1a was not consistently associated with the absence of DAZ1/DAZ2 copies and thus can be deleted with either DAZ gene pair. The absence of the DAZ and CDY1 copies was further confirmed by a densitometric analysis, according to Machev et al. In all the gr/gr and b2/b3 deletion cases, we found a reduction of gene dosage for DAZ and CDY1. We have therefore no case of b2/b4 duplication among the men with deletions.

Genotype–phenotype association

Both types of deletion were associated with a wide range of sperm parameters, from azoospermia to normozoospermia (table 1). Although the mean values of the three principal sperm parameters were lower in patients with gr/gr deletion than in patients without, the difference was not significant: 2.1 v 4.5 million spermatozoa/ml for mean sperm concentration, 12.8% v 20.8% for sperm motility, and 11.6% v 15.3% for morphology. As CDY1a deletion was a specific feature of the patient group, we calculated the frequency of gr/gr deletions with missing CDY1a in both patients and controls; the difference between the two groups was highly significant (p<0.003). It is therefore possible that only specific patterns of partial deletions are deleterious for spermatogenesis.

We also sequenced the entire coding sequence of DAZL to test whether allelic forms of DAZL might underlie the phenotypic variation associated with the partial deletions. We found no new mutations. Only one single nucleotide variant (SNV) was found, at nucleotide position 260. Two patients were heterozygous for this SNV; however, its incidence in normospermic and infertile men is similar and thus it is unlikely to have any significant effect on the phenotype.

Genotype–Y chromosome haplotyping and phenotype relationship

Recent studies reported that b2/b3 (u3-gr/gr or g1/g3) deletions primarily arise in one family of closely related
Y chromosomes (hgrN). The three b2/b3 (g1/g3) deletions found in our study were observed in three different Y chromosome backgrounds (hgr J and DE in two oligospermic patients and N3 in a normospermic man). In previous studies, gr/gr deletions were found to occur on different Y chromosome backgrounds, in our cases on hgr P, J, DE, and Y*

DISCUSSION

Classical AZF deletions, defined by a few well designed markers,20 are clinically relevant because a clear cause–effect relationship between these deletions and spermatogenic failure has been established.1 Owing to the absence of such deletions in normospermic men, the screening for AZF deletions has become part of the routine diagnostic investigation of the infertile male. The complete absence of the AZFa interval is associated with the most severe phenotype (complete absence of germ cells in the testis), whereas deletion of the entire AZFb region is associated with spermatogenic arrest (in general at the stage of primary spermatocytes).21 Deletion of the AZFc region can lead to different degrees of spermatogenic failure, with a significant variability between individuals, ranging from the absence of germ cells in the testis to the presence of spermatozoa in the ejaculate (oligospermia). These genotype–phenotype correlations refer to the three classical AZF deletions, and further data are needed to better define any clinically relevant difference between the so called classical AZFb (P5/proximal P1) and the two newly identified AZFb+c (P5/distal P1 and P4/distal P1) deletions.

Figure 1  Schematic representation of the proposed two step analysis for the detection of partial AZFc deletions. (A) the first step based on a PCR duplex with sY1191/1291 (alternatively, with a1084/5 and o1276/7) shows the four different possible outcomes of the analysis: b1/b3, gr/gr, b2/b3 (or u3-gr/gr or g1/g3), or absence of deletion; (B) the second step defines the breakpoints of the deletions.
In contrast to the situation for the complete AZFc deletion, genotype–phenotype correlations for the partial AZFc deletion seem to be more complicated. Using an STS +/− approach\(^9\) we found two types of partial AZFc deletion, gr/gr and b2/b3 (u3-gr/gr or g1/g3) in our study population. Both deletion types were present in the normospermic group, indicating that these deletions, in contrast to b2/b4 deletions, are not specific for spermatogenic failure. The gr/gr deletion seems to be more frequent than b2/b3 (or u3-gr/gr) in our Italian cohort (73% of the deletions were gr/gr). The similar frequency of the b2/b3 deletion in patients (1.3%) and controls (0.5%) does not support a pathogenic role for this

![Figure 2](image-url)
deletion; however, it has been found at high frequency in the general population of northern Europe in association with hgrN, indicating that hgrN may contain compensating Y linked factors.12 13 Our normospermic man with b2/b3 (or u3-gr/gr) deletion was hgrN3, whereas the two oligospermic men were hgrJ and hgrDE. Although the number is low, we can speculate that b2/b3 (u3-gr/gr; g1/g3) deletions are pathogenic only in association with certain haplogroups.

The frequency of gr/gr deletions was significantly higher in the infertile group with respect to controls, suggesting a possible deleterious effect of this polymorphism on spermatogenic efficiency. Similarly to the Repping study,29 the significant OR (10.1) indicates that gr/gr deletions can be considered as new risk factors for oligozoospermia. Although the mean sperm parameters (concentration, motility, and morphology) were not significantly different in the infertile group between men with gr/gr deletions and those without, there was a clear trend toward lower values in the former.

However, the most intriguing phenomenon observed in association with this type of deletion is the extreme heterogeneity of the phenotype, ranging from azoospermia to normozoospermia. In order to gain more insight into this phenomenon, we performed mutational analysis of DAZL, an autosomal homologue of DAZ. DAZ was copied to the Y chromosome relatively recently, in the old world primate lineage, and is 90% identical to its autosomal ancestor DAZL.30

We found no new mutations in the entire coding region of DAZL, and the polymorphic Thr12-Ala change (T12A) does not seem to have any modulating effect, probably because of its relatively high frequency in the normospermic group. However, as our mutational analysis was focused exclusively on the coding regions, we cannot exclude promoter variations that might affect the level of expression of DAZL.

Interestingly, deletion of the CDY1a copy was found only in the patient group, providing an even more significant difference (p<0.003) between the infertile and normospermic group. A similar phenomenon has also been observed in another study population from Mediterranean France.13

The different combinations of loci found deleted in cases of partial AZFc deletion indicate that a number of possible inversion events must have preceded these deletions.6 10 11 Clearly, the type of missing gene copies and the Y chromosome structure (hgr) on which the deletion arises are of fundamental importance for the understanding of a potential cause–effect relationship. Our data seem to support the hypothesis that DAZ1/DAZ2 copies are functionally more important than DAZ3/DAZ4,23 as the former were missing only in the patient group (p = 0.037); however, a recent study found no difference in DAZ1/DAZ2 deletion frequency between infertile men and fertile controls (with unknown sperm count), which appears to contradict this observation.31 On the other hand, our observation that deletion of CDY1 is strongly associated with infertility is consistent with the findings of this same study.29 This now requires further confirmation.

Although it is clear that the STS +/- analysis alone does not provide information about the type of missing gene copies and the hgr, we propose a flow chart (fig 1) in order to carry out partial AZFc deletion analysis in a cost effective and relatively simple manner. At this point, it is difficult to decide whether routine screening for partial AZFc deletions will be worthwhile. Clearly, gr/gr deletions, especially those resulting in the loss of CDY1a, can be considered a risk factor. However, the ideal situation would be to define a genetic profile specific for spermatogenic failure, although this may not exist.

Future studies in larger, well selected groups of subjects (patients without interfering abnormal andrological findings and normospermic controls) should focus on the combined definition of the type and copy number of the AZFc genes deleted in men with partial deletions and the haplogroup of the Y chromosome. This will probably provide a means of distinguishing between pathogenic and neutral (or compensated by other Y factors) deletion types. If we consider that, together with the gr/gr deletion, other Y related factors (protective or negative) will be transmitted to the male offspring, we can eventually propose screening for partial AZFc deletion prior to assisted reproductive techniques. However, until a clear definition of pathogenic and non-pathogenic deletions is established, the prediction of the testicular phenotype of the offspring will remain rather vague.

ACKNOWLEDGEMENTS

We are grateful to Dr M Rotondi for his valuable contribution to the statistical analysis of our data. We thank the clinical staff of the Andrology Unit and Reproductive Physiology for patient's recruitment: Professor M Maggi, Dr G Corona, Dr M Magini, Dr L Petrone, Dr A CCONTI, Professor E Coccola, Professor I Noci. The study was supported by a grant from the University of Florence.

The Letter to JMG titled, Ancestral RET haplotype associated with Hirschsprung’s disease shows linkage disequilibrium at –1249 (J Med Genet 2005;42:322-27) should have been published as a short report and the following abstract was omitted:

Background: Hirschsprung disease (HSCR) is a complex disorder with traditional germline mutations in RET in up to 50% of familial cases and in 3% of sporadic cases in a population-based series. We have previously demonstrated that an ancestral haplotype at the 5’ end of RET (haplotype 0) was strongly associated with a large subset of isolated HSCR cases and that a putative low penetrance susceptibility locus was encompassed within this ancestral haplotype, anchored by exon 2 SNP A45A.

Objective: To determine the 5’ extent of the HSCR-associated ancestral haplotype by defining the linkage disequilibrium breakpoint in search for the low penetrance susceptibility locus.

Methods: Systematic screening of the region upstream of the anchoring A45A SNP, comprising RET intron 1, exon 1, and promoter in 117 population-based HSCR cases and 100 controls. Dual luciferase assay to determine differential activities between SNP combinations near a transcription start site.

Results: New SNP’s were found which formed upstream haplotypes, anchored by A45A, in linkage disequilibrium with HSCR (χ² = 76.96, p<0.0000001). Linkage disequilibrium appeared to break at the –1249C/T SNP. Further, the HSCR-associated genotype (00) was found in >60% of HSCR but only 2% of controls. Because only 2 variants, -200A>G and –196C>T, lie within the promoter region and are in proximity to the transcriptional start site (at –195), we modelled these combinations into constructs for luciferase reporter assay. The HSCR-associated SNP combination showed the lowest activity and the control-associated combination, the highest.

Conclusions: Our observations seem to discard the existence of a HSCR-causing mutation as it is conceived in the traditional fashion. The data derived from our functional “in vitro” studies would suggest that the HSCR-associated haplotype 0 may result in a lower level of expression of the RET gene. The journal apologises for this error.
